4–8 August 1990

Editorial Communications

All manuscripts and editorial correspondence, except as noted below, should be addressed to:

Peter J. Barry, Editor
Department of Agricultural Economics
University of Illinois
305 Mumford Hall
1301 W. Gregory Drive
Urbana, Illinois 61801

Communications concerning book reviews and books submitted for announcement in the ***Journal*** should be sent to the book review editor:

Dale W Adams
Department of Agricultural Economics
Ohio State University
2120 Fyffe Road
Columbus, Ohio 43210

Editorial Policy

The purpose of the ***Journal*** is to provide a forum for creative and scholarly work in agricultural economics. Thus, acceptable manuscripts should have a relationship to the economics of agriculture, natural resources, or rural and community development. Contributions, methodological or applied, in the business, extension, research, and teaching phases of agricultural economics are equally encouraged. The ***American Journal of Agricultural Economics*** (ISSN 0002-9092) is published monthly in February, May, August, November, and December by the American Agricultural Economics Association, 80 Heady Hall, Iowa State University, Ames, Iowa and printed by Edwards Brothers, Inc., Ann Arbor, MI. Second-class postage is paid at Ames, Iowa, and additional mailing offices. Postmaster: Send address changes to the American Journal of Agricultural Economics, 80 Heady Hall, Iowa State University, Ames, Iowa, 50011-1070.

Subscription

Subscription cost is $65 per year plus foreign postage; members receive copies as part of their membership fee of $45 per year.

Books Reviewed

years, legislation has curtailed some farm tax shelters while enhancing or creating others. For example, the 1969 tax act required some orchard owners and all Christmas tree growers to capitalize and depreciate certain development costs, and it subjected depreciation on some buildings and livestock structures to recapture as ordinary income. The Tax Reform Act of 1976 restricted the tax deductions of limited partnerships investing in feed lot operations. In contrast, the Revenue Act of 1978 created the tax shelter possibilities afforded by single-purpose livestock structures. The 1981 tax act introduced the Accelerated Cost Recovery System (ACRS), which reduced the tax life of most farm equipment from ten to five years.

The Tax Reform Act of 1986 contained provisions that are likely to have substantial impacts on tax shelter investment in agriculture as well as other industries. A major goal of the legislation was to reduce the scope of farm investments that are motivated by income tax incentives rather than economic considerations (Hanson and Bertelsen). Farming activities must now produce a profit in at least three (rather than two) of the last five years in order to satisfy the farming-for-profit test.[1] Long-term capital gains will be fully taxed when realized, and enactment of "passive" loss rules will restrict the ability to offset other income with farming losses. The 1986 tax law replaced ACRS with an approach which will increase the length of time over which capital assets can be depreciated. The investment tax credit has been repealed, and preproduction expenses must now be capitalized rather than deducted if the development period exceeds two years.

A major impact of the provisions in the 1986 law which broaden the tax base is a likely reduction in the kinds of agricultural investment which have attempted to exploit accelerated depreciation, the capital gains exclusion, and current expensing of development costs. For example, Lins, Offutt, and Richardson suggest that investments in livestock breeding and orchards can be expected to fall because of the new passive loss rules combined with the required capitalization of preproduction expenses.[2] However, farm tax shelters are unlikely to be completely eliminated as a result of the 1986 law's changes relating to the measurement of taxable income. For instance, the hobby loss rules have never been a very effective limitation on farm losses, and the IRS does not have the resources necessary to examine every tax return for compliance with the passive loss and other rule changes.

Another important feature of the Tax Reform Act of 1986 which also may affect agricultural investment is the reduction of fourteen marginal tax rates, which ranged from 11% to 50%, to only two rates—15% and 28%. (Some taxpayers will confront an effective rate of 33% because of surcharges.) If high tax rates encourage investment in tax-preferred assets, then farm tax shelter investment can be expected to decline apart from any reduction coming from changes in the new tax law which affect the legality of farm tax shelters. The effect of changes in marginal rates of income taxation on tax shelter investment is discussed in the next section.

Taxation and Investment Choices

Previous research on the economics of income tax preferences provides important theoretical insight into the relationship between tax rate changes and tax shelter investment. In an often-cited 1974 paper, Bailey examined the implications of preferential tax treatment for portfolio choice and investment yields. In his analysis, preferential taxation was exemplified by the failure to tax fully the return on an investment. If the proportion of the before-tax yield which is taxed is a variable α, than $\alpha < 1$ indicates preferential taxation and $\alpha = 1$ implies full taxation. Bailey assumed that the before-tax return r^b decreases as the percentage of an asset's income taxed falls, other things the same, such as risk and transactions costs. In other words, an asset whose income is only partially taxed will command a premium that reduces its gross rate of return, or $\alpha_1 < \alpha_2$ implies $r_1^b < r_2^b$. Furthermore, competition will equalize after-tax rates of return r^a among individuals facing a given marginal tax rate t, where $r^a = r^b(1 - \alpha t)$.

In Bailey's analysis, an individual investor selects the asset yielding the highest after-tax rate of return. The tax-preferred status of the asset selected will depend on the investor's marginal tax bracket. There exists a "break-even" tax rate t^*, which equates the after-tax yields from any two assets with before-tax returns of r_1^b and r_2^b, with $r_1^b < r_2^b$ and $\alpha_1 < \alpha_2$. As shown by Galper and Zimmerman, $t^* = (r_2^b -$

[1] An interesting exception is that activities that consist primarily of breeding, training, showing, or raising horses need show a profit in only 2 out of the last 7 years (U.S. Department of Treasury 1987).

[2] However, the capitalization requirements with respect to animals have been repealed beginning in 1989.

$r_1^b)/(\alpha_2 r_2^b - \alpha_1 r_1^b)$. The implications for investment choice are straightforward. An investor facing a tax rate above t^* should choose the asset whose gross return r_1^b is relatively low but which yields the higher net return because of more preferred tax treatment (low α_1). Similarly, taxpayers facing an even higher tax rate should hold even more preferentially taxed assets, other things constant.

Bailey's general conclusion that high-bracket taxpayers tend to invest in tax-preferred assets is one of several results obtained more recently by Cordes and Galper, who explicitly investigated the effect of tax rate changes on the amount of investment in partially taxed assets. They outlined a general model in which the economy's fixed stock of physical capital is divided between investments in fully taxed assets (K_f) and tax shelters (K_s), which are defined as investments whose returns are not fully taxed. The gross returns to fully taxed capital (r_f) and tax-shelter capital (r_s) diminish with their levels of usage. The model assumes further that capital is mobile and that investors will allocate their wealth between tax shelter and fully taxed investments so as to equalize the after-tax, risk-free, return to capital. Symbolically, in equilibrium $r_s(1 - \alpha t) = r_f(1 - t)$, where t is the marginal income tax rate and α is the fraction of the return to K_s subject to tax, with $\alpha < 1$.

In the absence of taxes ($t = 0$), capital suppliers require that K_s earn the same return as K_f; that is, r_s must equal r_f or $r_s/r_f = 1$. When taxes exist but are neutral in the sense that all returns are fully taxed ($\alpha = 1$), $r_s(1 - t) = r_f(1 - t)$, which implies that r_s/r_f must again equal unity. In other words, if tax shelters do not exist, the rate of taxation does not affect the allocation of capital between assets in the Cordes-Galper model.

When tax shelters exist and all investors confront the same tax rate, capital market equilibrium implies that $r_s/r_f = (1 - t)/(1 - \alpha t) < 1$. This result requires that the share of capital used in tax shelter activities increase, relative to the capital allocation in the no-tax or neutral-tax case. Given the assumption of diminishing marginal productivity of capital, r_f will be relatively higher and r_s relatively lower in the single tax rate case. Because the relative return r_s/r_f declines as t rises, the model predicts that an increase in the tax rate will increase the amount of tax shelter investment. Once capital markets have adjusted to the higher tax rate, all investors will earn the same net return on investments.

Cordes and Galper show that when multiple tax rates exist, the impact of a tax rate change on tax shelter investment depends on the distribution of potential capital supplies among individuals facing different tax rates. At one extreme, taxpayers facing the top tax rate (t_h) may be willing and able to supply enough tax shelter capital to meet the entire demand, leaving fully taxed assets in the hands of individuals facing lower tax rates. Increasing tax rates across the board or just the top rate can be expected to raise the amount of investment in tax shelters. However, because the before-tax rate of return on tax shelter capital will decline as more is supplied, in equilibrium top-bracket investors will be unable to earn a higher net return on investment than owners of fully taxed capital.

If the top-bracket taxpayers cannot supply all the capital for tax shelters, then a similar sorting of investors by asset ownership is suggested by the model. Individuals facing t_h invest only in tax shelters, those facing a lower tax rate t_m hold both tax-preferred and fully taxed assets, and taxpayers facing a still lower rate t_1 purchase only fully taxed assets. The outcome in this case differs from the preceding one in two respects. The first, which is of primary concern given the focus of this paper, is that an increase in all tax rates will encourage more tax shelter investments, but changing only the top marginal rate does not necessarily affect the amount of tax shelter activity. Second, investors in the highest tax bracket will enjoy a higher net return than they could receive from fully taxed assets. This occurs because the before-tax return on tax shelter assets must be high enough to attract capital from investors in tax brackets lower than t_h. That tax shelters provide opportunities for arbitrage when multiple tax rates exist is often illustrated by the high net return which top-bracket investors receive on state and local government bonds (Goode).

Both the Bailey and the Cordes-Galper analyses suggest that an individual's willingness to supply capital for tax shelter investments varies directly with the marginal tax rate; thus, a tax rate increase generally can be expected to raise tax shelter activity. However, these models are general in the sense that they posit a class of partially taxed assets but they do not explicitly consider all the specific instances of preferential tax treatment. In reality, individuals can choose to invest in agriculture, real estate, oil and gas extraction, corporate stocks, municipal bonds, tax-deferred pension plans, and numerous other real and financial assets whose returns are not fully taxed under the federal (and state) tax laws, especially prior to 1986.

The actual provisions of the tax code must be

examined to determine how the extent of preferential taxation varies by assets or industries. Based on their analysis of the tax laws and investments by individual taxpayers in 1972, Galper and Zimmerman concluded that oil and gas extraction and real estate operators were clearly the most favorably taxed 4-digit subindustries appearing in the S.I.C. code. However, livestock, feeding and breeding; fruit, tree, nut, and vegetable farming; and forestry were also identified as preferentially taxed industries, enjoying tax benefits similar to those in the motion picture production and distribution industry.

In summary, the theory outlined above implies that the amount of investment in agricultural tax shelters will be positively related to the marginal tax rate. Of course, empirical analysis must be undertaken to determine the magnitude of the effect of taxation on farm tax shelter investment.

Tax Return Data on Farming Activity

In this paper the use of farming for tax avoidance purposes is empirically investigated with tax return data. Statistics on farm income (or loss) reported on Schedule F of the Federal 1040 individual income tax return have been published for the years 1963 to 1986 (see table 1). During this period the number of personal tax returns reporting farming activity fell by 21%, which is consistent with the general movement of resources out of agriculture in the United States. Personal farm income in aggregate has been on a downward trend since 1973 (especially in real terms) that culminated in negative incomes (net farm losses) throughout the 1980s. In 1963 there were about one-half as many Schedule Fs reporting losses as there were showing farm profits. By 1974 the loss/profit ratio based on the number of tax returns had risen above unity, and it continued to move upward, peaking at a value of 2.11 in 1984. A similar trend can be noted by comparing the dollar amounts of farm profits and farm losses. In 1963 farm losses were only 40% as large as farm profits. In 1984 farm losses reported on Schedule Fs were over three times as great as farm profits. Some recovery in terms of farming profitability has occurred since the record loss year of 1984.

During the time period covered by table 1, the marginal federal tax rate facing many individuals exhibited an upward trend that was halted only by declining inflation rates and the statutory tax rate reductions enacted in 1981. State income tax rates also rose over much of the 1963–86 period. Consequently, these patterns of farming tax losses and individual income tax rates are consistent with the view that rising tax rates encourage agricultural investment intended to produce tax savings rather than food and fiber.

The approach followed here to test the impact of tax rates on farm tax shelter activity is to examine the amount of farm profit or loss reported by individual taxpayers in the same year. A cross-sectional comparison removes the influence on farm losses of factors such as general business conditions and tax rules, which change over time. A rich source of microlevel data on farm income is the Internal Revenue Service's *1983 Individual Tax Model File,* a stratified random sample of individual income tax returns.[3] Table 2 shows the incidence of farm profits and losses and the amount of net farm income reported on 1983 tax returns. Overall a Schedule F was included on about 2.7 million returns (see table 1), or 2.81% of the 96.3 million total individual tax returns filed for 1983. The number of Schedule F returns indicating a farm loss was 1.81 times as great as the number reporting profit from farming. The average net income from farming activity (based on all returns) was a loss of $96, whereas the average Schedule F reported a loss of $3,416. The total net income reported on Schedule F in 1983 was $−9.3 billion (see table 1).

This aggregate picture conceals substantial variation by income level in the incidence and value of farm net income. Specifically, the percentage of tax returns reporting a Schedule F loss rises dramatically as nonfarm income increases, from 1.32% in the under $25,000 category to over 12% in the top income groups. Among taxpayers whose net income from wages, salaries, capital, and other nonfarm sources exceeded $100,000 in 1983, net losses from farming were six times as likely as net profits. The skewed distribution of farm losses by nonfarm income has also been noted by Woods.

When filed by an individual taxpayer with very little income from nonfarm sources, a Schedule F is more likely to identify a true farmer than a tax farmer. In 1983 about 61% of all tax returns reporting farm activity came from the lowest nonfarm income category in table 2 and the av-

[3] The *1983 Individual Tax Model File* consists of a sample of actual personal income tax returns (forms 1040, 1040A, and 1040EZ) filed by U.S. citizens and residents. This data base is prepared by the Internal Revenue Service to simulate the administrative and revenue impacts of tax law changes and to provide statistical tabulations relating to the incomes and taxes paid by individuals. Additional details of these data are provided in Strudler and Jamerson.

Table 2. Percentages of Individual Tax Returns Reporting Schedule F and Mean Net Farm Income in 1983

Return Category	Number of Returns (1,000)	Percent Reporting Schedule F Loss	Percent Reporting Schedule F Profit	Mean Net Farm Income ($) All Returns	Mean Net Farm Income ($) Schedule F Returns Only
All returns	96,322	1.81	1.00	−96	−3,416
Returns with nonfarm income ($1,000) equal to:					
Under 25	66,532	1.32	1.17	−5	−201
25–50	23,422	2.61	0.60	−164	−5,109
50–100	5,414	3.37	0.76	−298	−7,215
100–200	736	6.39	0.97	−1,932	−26,250
200–500	180	9.14	1.37	−6,355	−60,466
500–1,000	27	12.40	2.09	−15,345	−105,901
over 1,000	11	12.77	1.85	−45,026	−307,975

erage farm profit per farm return was $\$-201$. Such low returns are probably more indicative of the economic problems that faced farmers (especially small ones) in 1983 than agricultural investment for tax avoidance purposes. Tax return losses from farming activity grow rapidly as nonfarm income rises and reach very high levels in the highest income groupings. For example, taxpayers in the one-half to one million dollar nonfarm income category who filed a Schedule F reported an average net loss of about $106,000 in 1983, and those with one million or more nonfarm income reported an average farm loss of $308,000.

It is difficult to exclude tax shelter motives as an explanation for this pattern of increasingly negative farm income as other income rises.[4] True economic losses are disadvantageous to low and high income persons alike. Accounting, or paper, losses are more beneficial to wealthy individuals because they generate relatively larger tax savings under the progressive federal income tax. Thus, the pattern of farming activity revealed in table 2 is consistent with the hypothesis that higher tax rates increase the demand for farm tax shelters. Farm tax losses might rise with income for other reasons as well, however. Higher-income taxpayers have greater access to credit, tend to be better informed about tax shelter investments, and may be less risk averse than lower-income persons. Or perhaps, as Woods joked, the rich are "lousier" farmers than the poor. In any case, a multivariate statistical analysis is required to isolate the tax rate effect from the impact of income on tax-loss farming investment.

Econometric Analyses of Farm Tax Losses

In this section a reduced-form model of farm losses reported by individual taxpayers is described and estimated on a subset of returns from the *1983 Individual Tax Model File*. Two measures of farm tax shelter investment are constructed to serve as dependent variables in the empirical testing: (1) the incidence of farm losses (*INCIDENCE*), which is measured by a binary variable equal to 1 if a taxpayer files a Schedule F reporting a net loss and 0 otherwise; and (2) the dollar amount of farm losses (*LOSSES*), a continuous variable equal to the absolute value of negative farm income. The equations estimated take the general forms:

$$(1) \qquad INCIDENCE = f(MTR, INCOME, MARRIED, AGE65, DEPS, PCTFARM),$$
$$(2) \qquad LOSSES = g(MTR, INCOME, MARRIED, AGE65, DEPS),$$

where the independent variables are defined below.

According to the theory of portfolio choice, the primary independent variable is the prein-

[4] This pattern does not result because the data analyzed happen to come from a year in which overall farm income was negative. Replicating table 2 using data for 1979, a profitable year for farming (see table 1), yields comparable results.

vestment marginal tax rate (*MTR*), which in this paper is the statutory tax rate which applies when income is measured as actual taxable income minus net farm income. Under this definition, the taxable income for measuring *MTR* exceeds the reported taxable income of individuals who report a net loss from farming activity. *MTR* thus measures the rate of tax savings generated by the first dollar of negative farm income. Using this so-called "first dollar," or preinvestment, tax rate minimizes the simultaneity problem that results when the marginal tax rate is based on actual taxable income (Feldstein).

Two measures of *MTR* are used in the empirical estimation. *MTR*1 applies when preinvestment income equals actual taxable income minus net farm income reported on Schedule F.[5] This approach does not accurately measure the tax savings associated with farming investment if some farm income is reported as a capital gain rather than farm profit. Investment in breeding and dairy livestock, for example, generates deductions that reduce farm profit or increase farm losses; but the sale of these livestock produces income ultimately reported as capital gains with no impact on Schedule F net income. Accounting for the farm loss without also deducting the resulting capital gain income would overstate the preinvestment marginal tax rate (*MTR*1).

Unfortunately, the *Tax Model File* does not identify the precise source of capital gains and losses except to separate gains or losses from sales of stocks, bonds, a principal residence, and so forth (reported on Schedule D) from those resulting from sales or exchanges of assets used in a trade or business (reported on Form 4797). However, a second marginal tax rate (*MTR*2) can be computed by assuming that for taxpayers filing a Schedule F all of the taxable income reported on Form 4797 is associated with the farm investment.[6]

These two marginal tax rate variables incorporate both federal and state income tax structures. The federal tax rate assigned each taxpayer was based on the 1983 rate schedule (U.S. Department of Treasury 1986) and incorporated the minimum tax provision. The state tax rate equaled that which would be applied if nonfarm income were reduced by the standard deduction amount and allowances for personal exemptions. Details of state income tax structures are summarized in Advisory Commission on Intergovernmental Relations. *MTR* equals $f + s - fs$ for itemizers and $f + s$ for taxpayers claiming the standard deduction on their federal returns, where f and s are the applicable federal and state marginal rates. When federal income taxes can be deducted on state returns, the combined tax rate equals $(f + s - 2fs)/(1 - fs)$.

The use of state tax rates provides an independent source of *MTR* variation (apart from that caused by income differences) that is helpful in isolating the pure tax-rate effect on farming activity. State marginal tax rates range from zero to the teens, so there is substantial variation in the combined federal and state *MTR* even among taxpayers having the same income level. For example, a married taxpayer whose taxable income from nonfarm sources equalled $110,000 would have faced a 50% *MTR* in 1983 if he resided in Texas or Florida (states with no personal income tax), whereas a similar individual living in New York would have confronted a 57% *MTR* (assuming deductions were itemized). Theory suggests that the latter individual would have more incentive to invest in farming (or other assets) as a tax shelter.

Because confidentiality rules prohibit the identification of state of residence on certain returns in the *Tax Model File*, for estimation purposes our sample excludes taxpayers having adjusted gross income (AGI) under −$200,000 or over $200,000. Taxpayers in the income levels included in our sample filed over 99% of the farm (Schedule F) tax returns received for 1983. Of the 25,369 farm returns (out of 2.71 million total) which do not identify state of residence, 20,232 reported a net loss from farming and 5,137 reported a net profit. These returns excluded because of confidentiality restrictions generated 12.4% of all net farm losses in 1983 but only 3.9% of farm profits. Therefore, the sample used for estimation is biased by the omission of very high (or low) income taxpayers who report substantially above-average net farm losses. Consequently, the estimated coefficient of *MTR* in the equations presented below is likely to understate the true impact of the marginal tax rate on farm tax losses. Two additional criteria were used for sample selection purposes. First, to remove possible bias caused by fluctuating incomes and to simplify measurement of the marginal tax rate, tax returns using income averaging were deleted. Second, taxpayers with negative nonfarm income were eliminated from the sample.

[5] Operationally, the amount reported on line 37 of the 1983 Form 1040 minus the amount on line 19.

[6] For the taxpayer reporting Schedule F income or loss, preinvestment taxable income equals line 37 (Form 1040) minus line 19 (Form 1040) minus line 15 (Form 1040) minus 40% of line 16 (Schedule D).

To control for the anticipated positive effect of income on tax shelter investments in agriculture, the amount of nonfarm disposable income (*INCOME*) is also included as an independent variable. *INCOME* equals nonfarm income minus the income tax liability that would have been due if farm income were zero. Because previous empirical studies have often found that demographic variables are related to taxpayer behavior, the farm loss equations also include the number of taxpayer dependents (*DEPS*) and dummy variables to identify taxpayers who are age 65 or older (*AGE*65) and who are married (*MARRIED*).[7] The expected impacts of these variables on farm tax losses are unclear, although elderly taxpayers may be less inclined to undertake investments that shift taxable income into the future. The final independent variable is the percentage of all tax returns in the taxpayer's state of residence which report any farming activity on Schedule F (*PCTFARM*). This variable is included to control for the effects on farming activity of climate, natural resources, and other variables that differ by state and that might otherwise be captured by the estimated coefficient of *MTR*.

[7] For instance, Clotfelter and Steuerle found that marriage and the presence of dependents raise charitable contributions. Long and Gwartney found that aggregate tax losses are relatively lower for elderly taxpayers and, in certain income ranges, are higher for married couples.

Table 3 presents the estimated determinants of the incidence of farm tax losses. Because the dependent variable is dichotomous, the equations were estimated using logit analysis. Equation (1) reveals that the probability that a loss from farming activity is reported on an individual tax return is positively related to the marginal tax rate, which in this case directly reflects the tax savings generated by the farm loss. Technically, the coefficients (β's) in table 3 describe the impact on the natural logarithm of the odds that a farm loss is reported, not the actual probability of reporting a farm loss. To determine the marginal impact of *MTR*1 on the probability (P) that a farm loss is reported, the formula $\Delta P/\Delta MTR1 = \beta_{MTR1} \cdot P \cdot (1 - P)$ was utilized, as explained in Pindyck and Rubinfeld. The *MTR*1 coefficient in equation (1) yields an elasticity of the incidence of farm losses with respect to the tax rate of 0.53. This estimate implies that a 25% cut in marginal tax rates (similar to that of the 1981 tax act) in the long run would reduce the overall incidence of Schedule F losses from 1.81% of tax returns (see table 2) to 1.57%, other things constant.

The incidence of farm losses also varies directly with the level of disposable nonfarm in-

Table 3. Logit Analysis of the Incidence of Farm Losses Reported on Individual Tax Returns in 1983

come. Married taxpayers are significantly more likely to report a tax loss from farming than other persons, but other demographic variables reflecting elderly status and family size are not statistically related to the incidence of farm losses. The positive coefficient of *PCTFARM* confirms that the greater the amount of farming activity in a state, the higher the incidence of Schedule F losses among taxpayers residing in the state, all else constant.

Equation (2) shows that the signs and magnitudes of the logit coefficients are basically unchanged when a broader concept of the income associated with the farm investment is used in the measurement of *MTR*2 and *INCOME*.[8] However, several of the estimated parameters change significantly (regardless of how the marginal tax rate and income variables are measured) when the logit model is estimated using just those taxpayers having nonfarm income above $100,000. In particular, equations (3) and (4) show that the *MTR* coefficients increase roughly fourfold, yielding a tax rate elasticity of the incidence of farm losses of approximately 3.5. This finding is consistent with a recent analysis of income tax avoidance by Long and Gwartney. Using 1979 tax return data, they found that the impact of higher tax rates on tax loss investments was substantially larger among individuals with preinvestment incomes above $80,000 (which corresponds to about $100,000 in 1983 dollars) than among lower-income taxpayers.

The level of nonfarm disposable income also has a relatively larger positive effect on farm loss incidence in the upper-income sample, whereas marital status exerts a much smaller impact on the incidence of a Schedule F loss. The latter finding is not at all surprising—"genuine" farmers are statistically more likely to be married than nonfarmers, and the high-income taxpayer sample excludes most real farmers. The *AGE*65 coefficient reverses sign in equations (3) and (4), but neither it nor the coefficient of *DEPS* is statistically different from zero. The control variable *PCTFARM* retains its positive sign and high significance level in the farm loss incidence equations for the high-income sample.

Table 4 presents the estimated determinants of the dollar amount of farm losses on individual returns that reported a Schedule F loss in 1983. The *Tax Model File* sampling weights were applied to the data to make the size of farm tax losses reported on sample returns representative of the parent population. Given the evidence in table 3 and elsewhere that upper-income indi-

[8] The fact that a different measure of nonfarm income was used to compute *MTR*2 explains the small difference in sample sizes between the even- and odd-numbered equations.

Table 4. Regression Analysis of the Dollar Amount of Farm Losses on Individual Tax Returns Reporting Schedule F Loss in 1983

Explanatory Variable	Nonfarm Income Less than $100,000[a]		Nonfarm Income Greater than $100,000[a]

[b] Indicates that the equation is statistically significant at the .01 level.

viduals engage in more tax avoidance when tax rates rise than lower-income persons, the regression model was estimated separately for two income groupings. Equations (1) and (2) reveal that when nonfarm income is less than $100,000, a unit increase in the marginal tax rate raises farm losses by about $500 to $600. In contrast, among taxpayers with nonfarm incomes over $100,000, a one percentage point increase in the marginal tax rate raises farm losses by either $4,743 or $5,729, depending on how *MTR* is measured. The elasticity of farm losses with respect to the marginal tax rate equals 2.49, 2.13, 4.22, and 5.17 in equations (1), (2), (3), and (4), respectively. Given that the coefficients of *MTR*1 and *MTR*2 are all statistically significant at the one percent level or better, the pattern of these tax rate effects suggests that usage of farming investments for tax-avoidance purposes does in fact rise with income.

According to equations (1) and (2), the level of nonfarm disposable income is negatively related to farm losses when income is less than $100,000. However, when nonfarm income exceeds this amount, farm tax losses expand with income. Actually, the first of these two conclusions is somewhat misleading. When the regression model was reestimated with the squared value of *INCOME* added, the results (not reported) indicated that the negative relationship between farm losses and income disappears once nonfarm income reaches about $54,000. This phenomenon may reflect the presence in the sample of genuine farmers who recorded true economic losses in 1983. It may also indicate that farm investments are income-inferior tax shelters for all but high income taxpayers. In any case, the finding that farm losses and *INCOME* are positively related (unless nonfarm income is relatively low) is consistent with the variation in net farm returns by income level illustrated in table 2.

When taxpayers with nonfarm income under $100,000 report a Schedule F loss, two of the demographic variables (*MARRIED* and *DEPS*) are positively and significantly related to the size of the tax loss. In contrast, farm losses are not consistently related to taxpayer characteristics such as age or marital status in the over-$100,000 sample. This finding lends additional support to the view that farm losses reported on high-income returns are the result of deliberate tax shelter investments in agriculture. If such investments were not primarily motivated by tax considerations, then one might expect some relationship between farm losses and noneconomic variables, as in the case of the impact of marital status and family size on investment in owner-occupied housing (Silberman, Yochum, and Ihlanfeldt).

In summary, the *MTR* coefficients in tables 3 and 4 are consistently positive and highly significant, suggesting that higher tax rates increase the incidence and amount of farm losses reported by individual taxpayers. While the use of agricultural investments for tax avoidance purposes has long been thought to occur, empirical evidence isolating the tax rate effect on farm losses has generally been lacking. The methodology employed to identify the tax rate effect involved a statistical comparison of taxpayers facing different marginal rates but operating under basically the same rules regarding the measurement of taxable income and tax liability. Consequently, the estimated marginal tax rate coefficients could be used to project the decline in farming tax-shelter activity accompanying a statutory reduction in tax rates, *ceteris paribus*. However, such projections would surely understate the anticipated decline in agricultural tax shelters following the 1986 Tax Reform Act because this legislation also contained numerous other provisions likely to deter tax-avoidance investment.

Concluding Comments

In this paper a variety of empirical evidence has been presented to suggest that an increase in personal income tax rates will induce individuals, especially high-income ones, to farm the tax code in order to shelter income from taxation. Consequently, recent federal tax rate reductions can be expected to reduce farm investments intended to produce tax losses rather than agricultural output. The conclusion that some income losses associated with farming activity are the byproduct of deliberate tax-avoidance investments in agriculture is not incompatible with the fact that many American farmers have confronted genuine financial hardships in the 1980s. Much agricultural investment is undertaken with the expectation of increasing income flows or capital appreciation, using tax advantages such as rapid depreciation and investment tax credits to help achieve these goals. Tax considerations are not the sole source of low aggregate farm incomes during recent years. However, recognition that some agricultural investment is tax motivated implies than an aggregate measure of the net income from farming is a misleading in-

dicator of true farming profitability because it conceals the tendency of farm losses to increase with investors' income levels.

The extent to which taxpayers utilize farming investments as tax shelters and the amount of nonfarm income avoiding taxation as a result may not be judged all that significant when compared to tax avoidance in aggregate or to other specific avoidance techniques such as real estate investment.[9] However, tax-loss farming may create some troubling side effects, such as bidding up the prices of farmland and other resources and subjecting genuine farm operators to competition with investors who consider farm profit in the economic sense as unnecessary for their purposes (Woods). Furthermore, farm tax shelters constitute yet another channel through which the personal income tax base is eroded by high marginal tax rates. Tax-loss farming illustrates the ingenuity and willingness of individuals to arrange their economic activities in order to minimize the tax burden. Consequently, tax policies designed to reduce high marginal tax rates are desirable from the standpoint of alleviating the resource misallocations and distributional inequities associated with agricultural and other tax shelters.

[9] For example, using a tobit analysis of aggregate income tax losses in 1979, Long and Gwartney estimated that among upper-income individuals a unit increase in the marginal tax rate raises losses by anywhere from $1,800 to $4,400. The determinants of farm tax losses have also been estimated with tobit analysis rather than with the two-step procedure that was reported in this paper. Both procedures imply that farm losses rise by no more than $400 with each percentage point increase in the tax rate.

Temporal Analysis of Income Earned by Former Agriculture Students

Warren P. Preston, Josef M. Broder, and Maria Cristina P. Almero

Earnings profiles of students formerly enrolled in a college of agriculture were analyzed in the context of labor market information. Analysis of covariance was used to estimate models explaining how salary determinants changed during the alumni's careers. Gender, education, year of job market entry, profit sharing, and personal emphasis on earnings were found to be significant determinants of starting incomes. Starting incomes were found to be a prime determinant of later year salaries along with experience on the immediate job, profit sharing, oral and technical skills, marital status, and place of residence. Labor market information was found to vary in quality across participants and have a limited shelf life.

Key words: careers, college of agriculture, compensation, human capital, job skills, labor market.

Conditions of imperfect competition characterize virtually all labor markets. Numbers of sellers (workers) or buyers (employers) often are small, especially for higher level positions. The goods offered for exchange are not homogenous because each potential employee offers a unique portfolio of abilities and skills. Market entry and exit are neither costless nor instantaneous. According to the Employment Management Association, companies spent an average of $5,856 to hire a professional or managerial employee during 1987 (*Wall Street Journal*). Relocation costs for employees also are substantial. Finally, information available in labor markets is far from perfect. Workers and employers possess different information sets that can be revealed selectively in the labor market. The result is an asymmetry of information among labor market participants.

Because of uncertainty, information regarding labor market conditions is of variable quality and is subject to differing interpretations. In particular, the market for graduates from colleges of agriculture illustrates differences in the assessment of available labor market information. Enrollments in both undergraduate and graduate agricultural programs have declined steadily over the past ten years (Suter). Undergraduate enrollments alone dropped by as much as 24% from 1980 to 1987. Such trends suggest that the market responded to perceptions of declining career opportunities in the agricultural sector. On the other hand, the same trends have led some observers to predict labor shortages of individuals with master's and doctoral degrees in high-technology disciplines within colleges of agriculture over the next ten to fifteen years (Coulter, Stanton, and Goecker). Surpluses or shortages of qualified individuals should not exist in perfectly functioning labor markets.

Information plays a critical role in the operation of labor markets. From an individual worker's perspective, labor market information evolves in step with stages of the worker's career. For example, newcomers to the labor force may be unknowledgeable about labor market conditions and their own capabilities. A search process among jobs may be necessary before individuals become established in an appropriate career track. At different stages of the career, the relative importance of various factors that influence salaries may change. Thus, there is a

The authors thank John A. Ballweg, David Orden, William J. Taylor, and two anonymous reviewers for helpful suggestions.

need to learn which factors are important in determining individuals' salaries and how these factors change over workers' careers.

The literature on labor markets for agricultural college alumni is limited. These studies have focused on curricula (Sjo, Orazem, and Biere; Kropp); on student characteristics, goals, and perceptions (Dunkelberger et al., Schrimper); on monetary returns (Broder and Deprey); on training (Roberts and Lee); and on markets for graduates (Schneider). A common feature of these studies is that each deals with only a single point of time. In particular, there is a lack of information about the relationship of individual characteristics to salary earned both on leaving college and after several years of labor market experience.

An analysis of the factors that contribute to the earnings of alumni would provide valuable information for potential employees, employers, and individuals responsible for student recruitment, curriculum design, and educational reform. Moreover, an examination of how income determinants may change over the course of a career would provide for even richer implications. Suitable recommendations for career advancement, for example, would be directly affected if income determinants vary with career maturation. The design of undergraduate and graduate programs in agriculture also is affected by the timing of payoffs to human capital investments. Curricular reform efforts aimed at increasing student enrollments may fail unless monetary returns to graduates are realized early in the career.

The purpose of this study is to determine the extent to which individual characteristics, educational backgrounds, and occupational experiences influence the earnings of former agriculture students over time. The study extends earlier research efforts by explaining entry level incomes of former students as well as later incomes, when some job experience has been gained. Of particular interest are changes in labor market information that occur as individuals gain work experience.

Respondent Characteristics

Data for the study were obtained from the S-200 research project ("Occupational Career Paths of Former Students in Southern Land Grant Universities") conducted jointly by southern land grant universities and the Cooperative State Research Service of U.S. Department of Agriculture (USDA). The S-200 project was begun in 1984 and followed up the S-114 project ("Defining and Achieving Life Goals: A Process of Human Resource Development") conducted during the late 1970s (Dunkelberger et al.).

Data for the S-200 project were obtained through a mailed questionnaire administered to a random sample of undergraduate students who were enrolled in agricultural programs during 1977. The mailed survey included questions on educational attainment, career mobility, college curriculum competencies and skills, opinions about agricultural careers, and other personal characteristics. A total of 296 former students from the College of Agriculture and Life Sciences at Virginia Polytechnic Institute and State University (Virginia Tech) received questionnaires as part of the S-200 project. The analysis presented in this paper is based on 243 usable responses. Although limited to one school, the sample is presumed to serve as a reasonable representation of the general population of agriculture students from land grant universities.

Educational Characteristics

Because the initial sample was drawn from students in various stages of their undergraduate programs, some of the respondents had changed majors before graduation. Thus, the survey included respondents who later earned nonagricultural degrees. Eighty percent of the respondents graduated from agriculture, 15% graduated from other colleges, and 5% did not graduate. Greater numbers of agriculture college students were in forestry (28.0%), followed by animal science (19.3%) and horticulture (7.8%). Students who switched to nonagriculture majors were in a variety of fields but with larger representation in business (2.9%), biological science (2.1%), and education (1.6%).

Educational attainment patterns show that 51% of the respondents terminated formal education with bachelor's degrees. Another 16% earned master's degrees, and about the same percentage completed other additional education beyond a bachelor's (such as M.B.A.s or technical programs). About 3.7% of the respondents earned professional degrees, such as M.D. or D.V.M. At the time of the survey, about 6% of the respondents were enrolled in master's programs, 3.7% in professional degree programs, and 2.5% in doctoral programs.

Labor Market Characteristics

Less than half of the respondents (40%) identified their first full-time jobs following college as having duties related to agriculture. This proportion remained nearly constant as respondents acquired labor market experience. By 1987, 39% of the respondents held jobs that they perceived as involving agriculture. Respondents earned an average starting annual salary of $16,926 (adjusted to 1985 dollars using the consumer price index) on the first job after college. Over three-fourths of the respondents earned under $20,000 on their first jobs. By 1985, respondent incomes averaged $24,160.[1] Fewer than one-third of the respondents reported 1985 personal income under $20,000.

Models of Earned Income

A central focus of this study was to determine how the importance of the various determinants of personal income may change during different stages of one's career. Given the expectation that the relative influence of income determinants would change over time, two separate models of personal earnings were developed. The first model attempted to explain income earned at the beginning of the respondents' careers. During the formative period of career development, little concrete information about job performance would be available. Employer's assessments of a prospective employee would tend to rely on indirect measures of career potential, such as performance in college and personal background.

Starting salaries were entered into the first model as the annual pretax salary earned on the first job after leaving college (hereafter, simply "starting income" or *INC*1). Starting annual salaries were converted to constant 1985 dollars to adjust for the effects of inflation over time because individuals started their first full-time jobs in different years. Excluded from the analysis were respondents who failed to respond to the question, for whom the question was not applicable, or who reported zero income.[2] Starting salary model estimates were based on 205 usable observations.

The second model attempted to explain respondents' earnings after several years of job experience. Work experience provides additional information to both sides of the labor market. Employers gain direct insights into employee job performance, while employees reassess job expectations and career potentials.

Respondent incomes were entered into the second model as the annual pretax income reported for 1985 (hereafter referred to as "1985 income" or *INC*2). Excluded from the analysis were those for whom the question was not applicable, those who did not respond, and those who started their most recent jobs after 1985. The 1985 income model estimates were based on 182 observations, 23 less than the starting income model. Sample differences were attributed to random events and thus were assumed not to be a potential source of systematic bias in model estimates.

With few exceptions, similar explanatory variables were selected for each model. An individual's potential earned income was hypothesized to be influenced by investments in human capital, which include formal education and labor market participation and training. Earnings might also be affected by labor market imperfections that enhance or impede labor resource mobility, such as job location, and personal characteristics including gender, age, and marital status.

Analysis of covariance (ANCOVA) estimates for both models were obtained using the SAS general linear models procedure (SAS Institute). ANCOVA is mathematically equivalent to ordinary least squares (OLS) regression with both continuous and appropriately defined dummy variables. Lacking sufficient theoretical or empirical evidence for alternative specifications, the models were specified as linear functional forms.

Starting Income Model Results

ANCOVA results for the estimated starting income model are given in table 1. The coefficient of determination (R^2) for the model is 0.29, and the overall model is significant at the 0.01 level. To examine for possible multicollinearity, a cross-correlation matrix for all explanatory variables was obtained. The resulting correlation coefficients were all less than 0.3, which is considered evidence of little if any correlation (Hinkle,

[1] Unlike the question regarding starting income, which was open ended, the question regarding 1985 gross personal income was posed as categorical choices to enhance response rates. Hence, the midpoint of each category was used to best approximate each income bracket for the 1985 data.

[2] Consideration was given to constructing a suitable framework for incorporating responses from those reporting no income. However, the number of such observations was too small to provide statistically meaningful results.

Wiersma, and Jurs). The expectations, specifications, and findings of individual explanatory variables are discussed below.

The year that respondents began their first jobs after college (*JOBYEAR*) was entered as a continuous variable, or covariate, in the starting income model. In light of common perceptions about declining career opportunities in agriculture during the past ten years, a negative coefficient on *JOBYEAR* was expected. The coefficient for the covariate *JOBYEAR* was negative and significantly different from zero. Thus, respondents who began their first job in later years received lower real starting salaries than those who began earlier. The lower earnings of those who began later likely reflect labor market adjustments in response to depressed economic conditions, higher interest rates, and other market forces. That is, later wage rates may reflect market clearing levels at lower prices for a given value of marginal product.

The educational attainment of the respondent when beginning the first full-time job (*EDUC*1) was entered as a class variable with three levels: "Bachelor's or Less," "Enrolled in Advanced Degree," and "Completed Advanced Degree" (includes master's, professional degree, or doctorate). The level of educational attainment was expected to have a positive impact on starting annual salary, with those possessing higher educational levels earning higher salaries (Chiswick). *EDUC*1 was significant as shown by the F-value calculated for Type III or partial sum of squares (SAS Institute).

Given that educational attainment accounted for differing levels of income earned by the re-

Farming the Tax Code: The Impact of High Marginal Tax Rates on Agricultural Tax Shelters

James E. Long

Surprisingly little scholarly work has examined the practice of "farming the tax code," in which accounting losses on agricultural investments are used to shelter other income from taxation. Economic theory suggests that the amount of investment in agricultural tax shelters is positively related to the marginal tax rate. This hypothesis is empirically investigated using a sample of federal individual income tax returns filed for 1983. Both the probability of reporting a farm tax loss and the amount of farm losses are increased by a rise in the marginal tax rate, especially among upper income taxpayers.

Key words: agricultural investments, empirical analysis, tax rates.

The 1980s have been bleak years for American farmers. Their financial problems, resulting from high real interest rates, depressed prices and agricultural export sales, declining farmland values, and climatic difficulties, have been widely discussed. Data on farm incomes reported to the Internal Revenue Service substantiate these financial hardships. For example, individual taxpayers have reported aggregate net losses from schedule F (farm) activities in every year since 1980, with the cumulative total farm losses for 1980–86 exceeding $60 billion (see table 1).

Some portion of farm losses, especially those reported on individual tax returns, may not be the direct result of adverse business conditions in the farm sector. Because agriculture has long enjoyed preferential tax treatment, many individuals reporting farm losses may in fact be "farming the tax code" rather than the soil. Recent studies of taxpayer behavior have shed much light on the numerous ways in which individuals avoid taxation in the face of high marginal tax rates. These ways include tax evasion (Clotfelter 1983a), substituting fringe benefits for taxable compensation (Long and Scott, Woobury), consuming tax-deductible goods and services (Clotfelter 1983b, Long and Gwartney), deferring realized capital gains (Lindsey), and real estate partnership investments (Long and Gwartney).

Surprisingly, almost no scholarly work has reported the extent to which upper income taxpayers farm the tax code, although this practice has been widely acknowledged. Noting that income tax returns for 1966 and 1970 revealed that a large amount of farm losses were reported by taxpayers who had high nonfarm incomes, Woods suggested that either people were exploiting the tax code or the rich made "lousy" farmers. Davenport, Boehlje, and Martin expressed a similar view when they stated, "Were agriculture less tax favored than it is, . . . there would be fewer high-bracket taxpayers in farming" (p. 30).

The primary purpose of this paper is to investigate empirically the tax shelter motive for agricultural investments by individuals. In the next section, some of the major tax provisions affecting farming are briefly discussed, including those contained in the Tax Reform Act of 1986. A theoretical discussion of investment choices and preferential taxation then is presented. Individual tax return data pertinent to the tax shelter aspect of farming also are presented and the relationship between farm losses and the rate of taxation is analyzed econometrically.

Agricultural Tax Preferences—Before and After 1986

American agriculture has enjoyed a variety of general and specific income tax preferences since

Source: *Individual Income Tax Returns*, annual (1963 to 1985); Kalish and Shiley.
[a] na, not available.

1915. A detailed description of these preferences can be found in numerous government and academic publications dealing with farm taxation; for example, see Niles, Woods, Sisson, Moore, Krause and Shapiro, and Carman. The most important tax advantages have included (*a*) the option to use cash accounting, which requires no inventory records and allows input expenses to be deducted in the year actually paid even if they produce no income in that year; (*b*) tax regulations that permit farm assets such as livestock, real estate, and timber to qualify for long-term capital gains taxation; (*c*) accelerated depreciation of animals held for breeding purposes, single-purpose livestock structures, plants and trees, and certain other items; and (*d*) the ability to deduct the cost of developing certain capital assets, including the cost of raising dairy or breeding livestock and the cost of developing orchards and vineyards. Provision (*d*) has been particularly important in terms of enabling investors to convert ordinary income into long-term capital gains that, prior to the Tax Reform Act of 1986, were not fully taxed.

A different kind of tax benefit is that farming may provide an opportunity to participate in sporting or leisure activities such as horseback riding, hiking, hunting, and fishing. Someone once remarked that the best tax shelter is a business that permits an individual to deduct the cost of doing what he enjoys. Furthermore, there is no tax due on any nonpecuniary income or personal utility provided by farm assets, whether it be the pleasure obtained at a rural retreat or the excitement and prestige associated with breeding and racing thoroughbred horses. Recognizing that agricultural assets may pay off in different ways, Bullock suggested that much investment in U.S. agriculture is motivated toward "consuming" a rural way of life rather than generating a competitive rate of return.

The Internal Revenue Service has taken actions to prohibit some of the most flagrant tax avoidance schemes involving farming and other industries as well. In the case of the "hobby" farm, tax deductions are limited, and no farm losses can be used to offset other income if the IRS determines that the farm is not operated to make a profit (and the taxpayer cannot demonstrate an intention to make profits). Over the

spondents, the next step of analysis identified significant differences between the three levels of *EDUC*1. Parameter estimates for each level within the class variables are shown in the right-hand column of table 1. The reported coefficients correspond to coefficients that would have been obtained under OLS estimation with dummy variables. For *EDUC*1, "B.S. or Less" serves as the omitted dummy variable.

The least squares means procedure in SAS provided the complete difference of means tests for significant explanatory variables. A 0.10 level of significance was specified for all difference of means tests. Complete analysis of the significant variable *EDUC*1 entailed three paired comparisons among the three levels within *EDUC*1. Specifically, paired comparisons showed that those with advanced degrees earned significantly higher salaries than those with only a bachelor's and those enrolled in an advanced degree program. Salaries for those with bachelor's degrees or less and those enrolled in advanced degree programs did not differ significantly from each other. The significantly higher salaries earned by advanced degree recipients give further confirmation to the notion that more education leads to higher annual salaries.

Respondents' majors were entered as a categorical variable to account for possible variations in earnings attributable to the college major. There were three levels for the variable *MAJOR*: "Nonagricultural," "Agricultural (Non-Forestry)," and "Agricultural (Forestry)." School of Forestry majors were classified separately from other College of Agriculture majors to obtain more homogenous units with respect to training and possible career choices. Furthermore, because all of the respondents initially were enrolled in the College of Agriculture, results of the *MAJOR* variable would show whether transferring into other colleges affected later earnings. Parameter estimates pointed toward higher starting salaries for those who transferred to majors outside agriculture than for those who remained in agriculture. These differences, however, were not statistically significant.

The binary variable *SOUTH*1 identified whether the first job was located in one of thirteen southern states. Because wage rates in the South generally lag behind other regions, those who obtained jobs outside the South were expected to earn higher incomes (Broder and Deprey). The parameter estimate suggested higher salaries for individuals located outside the southern region. However, the computed F-value showed that *SOUTH*1 did not contribute significantly to explaining the variation in starting incomes, suggesting that job region was not an important determinant of starting salaries. This finding was attributed to Virginia's status as a regional transition state.

The contribution of job placement institutions (*PLCMT*) was entered as a categorical variable with four levels. The categories included "University Services," such as the placement office, dean's office, or faculty member; "Private Services," such as public or private employment agencies; "Individual Efforts," such as civil service application, employment advertisements, direct applications, military service, self-employment, or others; and "Personal Networks," such as contact of a relative or friend, or a return to a family business or farm. Human capital theory suggests that individuals maximize their economic welfare given the costs of their investments. The *PLCMT* variable was included to determine if "who you know" rather than "what you know" made a difference in salaries earned on the first job. Results showed that the path followed to find the first job did not make a significant difference in determining first job starting salaries. Although "knowing the right people" may have contributed to finding the first job, it made little apparent difference in the salary earned.

A binary variable (*AGJOB*1) indicated whether the respondent's job involved farming, agribusiness, or neither. The *AGJOB* variable was included to detect possible differences in starting salaries between those employed in farming and in the agricultural and nonagricultural sectors. Results suggested that the nature of the job was not an important determinant of starting salaries. With respect to earnings, then, the respondents fared the same in both the agricultural and nonagricultural sectors. Although not significantly different from zero, parameter estimates suggested that those engaged in farming received about $2,000 less in starting salaries than those not involved in farming.

Respondents' rankings of the importance of pay in their decisions to accept their first jobs was included as a class variable. The two levels for the *PAY* variable were "Not/Somewhat Important," and "Important/Very Important." *PAY* was used to determine how the perceived importance of monetary returns affected earnings and to account for nonmonetary factors in career choices. Because pay is an indicator of the return to investments in human capital, respondent perceptions of its importance were assumed to show the degree to which financial compen-

sation influenced the selection of initial employment. Higher earnings were expected for those considering pay as important or very important. Results showed that the variable *PAY* contributed significantly to explaining the variation in starting income. Parameter estimates indicated that those who rated *PAY* as important or very important earned mean starting salaries $2,928 higher than those who viewed *PAY* as not or somewhat important.

The fringe benefit profit sharing (*PRFT*1) was entered as a binary variable indicating whether the respondent participated in a profit-sharing plan. As added monetary compensation, profit-sharing benefits were expected to be a positive determinant of earnings. That is, the provision of profit-sharing benefits was hypothesized to be directly associated with earnings, with more provided at higher income levels. Respondents were assumed to have included their earnings from profit sharing in their reported incomes. *PRFT*1 was found to be significant. Respondents who were provided with profit sharing benefits earned mean starting incomes $2,291 higher than those without such benefits.

A binary variable (*HSG*1) was included to indicate the provision or nonprovision of housing benefits. As nonmonetary compensation, the provision of housing was expected to be inversely associated with earnings. Although parameter estimates suggested that respondents with housing benefits received lower mean starting salaries than respondents without housing benefits, the difference was not statistically significant.

Gender has been a significant factor in explaining variations in earnings, with males earning significantly higher average salaries than females (Ferber, Green, and Spaeth; Lewis and Emmert; Remus and Kelley; Broder and Deprey). *GENDER* was entered as a binary variable and was found to be significant in explaining the variation in starting income. Parameter estimates showed that starting salaries of males averaged $1,733 more than that of females. Results for the *GENDER* variable are consistent with the voluminous literature on the salary differential between the sexes. An explanation based on human capital arguments is that females may lack resource mobility because of personal interests and family, which greatly restricts their potential earnings. Combined with employer perceptions that women may be greater hiring risks because of possibly higher turnover rates, lower salaries can be interpreted as risk premiums for hiring females. Employers may pass some of these risk premiums on to female employees as lower salaries.

The starting income model included two variables related to retrospective opinions about the importance of skills and competencies gained in college to the respondents' own careers. The variables represented proxy measures of interpersonal skills (*ORAL*) and technical skills (*TECHNICAL*). The skills were classified as being either "Not/Somewhat Needed" or "Much Needed/Essential." Neither variable contributed significantly to explaining the variation in starting incomes.

1985 Income Model Results

The 1985 income model used continuous and categorical variables in an analysis of covariance. Gross personal income was used as the dependent variable. The analysis of covariance for the estimated model is given in table 2. The coefficient of determination for the model was 0.33.

Compared to labor market attributes applicable to the starting income model, more complete market information was available for the 1985 model. In particular, the survey respondents had acquired some job experience and a salary history by 1985. Job experience represents personal investment in human capital, especially for entry-level positions. Salary history provides additional conditioning information to both employers and workers themselves.

1985 earnings were expected to be sensitive to initial market assessments of employee potential as reflected by starting income. Starting income denotes the outcome of search processes conducted on both sides of the labor market. From the employee's perspective, acceptance of a job suggests that the expected costs (including opportunity costs) of continuing the job search exceed the expected benefits (in the form of greater monetary or nonmonetary returns). Likewise, the employer's decision to hire an individual suggests that the expected costs for continuing the search for a better candidate exceed the expected marginal benefits. Thus, starting income represents a mutual assessment of an individual's competitive position in the labor market and was expected to be a positive determinant of 1985 income.

Model results showed that starting incomes had a positive and significant impact on 1985 incomes. The description of the data showed that the respondent's real incomes in 1985 were larger

than their starting real incomes. However, the coefficient on starting income was less than one, indicating that later incomes were not the result of a simple linear growth of starting incomes. Other factors must have accounted for the real growth of individual's incomes.

The influence of starting income on 1985 income may be indicative of imperfections in labor market search processes. Salaries generally, and starting salaries particularly, are subject to random variation primarily because of imperfect information. For example, an adept bargainer may squeeze out a higher salary compared to a better qualified counterpart hampered by inferior negotiation skills. The results suggest that both random and systematic salary differences at the beginning of the career continue to influence salaries earned later in the career. The effect, however, dampens over time as shown by the coefficient of less than one on starting income.

The 1985 income model included two variables to account for human capital acquired by individuals through job experience. The sum of the variables (*EXPER*1 and *EXPER*2) equals the total number of years since a respondent began the first job. *EXPER*2 measures the length of employment on the most recent job held by a respondent; *EXPER*1 measures the length of all previous employment. The rationale for separating employment experience into two components was to capture differential effects of the information conveyed by each of the measures. It was hypothesized that the labor market emphasizes experience acquired on the immediate job over experience gained on earlier jobs. This hypothesis results from the operation of two forces. First is the development of human capital. Human capital acquired on a particular job has immediate application and thus should have a quick payoff. Human capital investments made through prior job experience may have limited

or tangential application to a later job and may obtain returns which are lower than that realized from immediate job experience. Time is the second force in operation. The value of both information and human capital investments deteriorate over time. Information about performance on earlier jobs may be discounted more heavily as more information about performance on the immediate job becomes available. Just as with machinery, human capital depreciates and therefore must be replenished through continual maintenance and reinvestment. Consider, for example, the decline in the value of keypunch operation skills over the past two decades.

Model results for the two measures of experience were in accord with expectations. The coefficient on prior job experience (*EXPER*1) was positive but not significantly different from zero. The coefficient on the length of employment on the immediate job was both positive and significant. Respondents earned an average return of $972 for each year of employment on the most recently held job. These results confirm the hypothesis that immediate job experience is more highly valued in the marketplace than earlier job experience.

The educational variable *EDUC*2 (highest educational level achieved by 1985) was insignificant in the 1985 income model. This does not imply, however, that advanced degrees yielded zero returns once the respondents had acquired some job experience. Recall from the first model that there was a $3,102 premium in starting income for an advanced degree. The premium carries into the 1985 income model through the starting income variable (*INC*1). For 1985, then, an advanced degree earned a premium of at least $1,002, which is the advanced degree carried over from the starting income model less the advanced degree "discount" in the 1985 income model ((0.563 × $3,102) − $744). The advanced degree premium for 1985 would be $1,746 (=0.563 × $3,102), considering the statistical result that 1985 incomes associated with the three levels *EDUC*2 were not significantly different from zero or each other.

The research hypothesized that the influence of job experience on salary rises with an individual's time in the labor force. Collective results on the job experience and education variables support this hypothesis. The increase in income from less than two years of experience on the immediate job (*EXPER*2) exceeded the 1985 income premium associated with advanced degrees. The findings show that the net returns to obtaining an advanced degree depend critically on the opportunity costs and length of the degree program. This result must be tempered, however, because the analysis did not account for possible differential income growth rates associated with levels of formal education. *MAJOR* was found to have a statistically insignificant influence on 1985 incomes, consistent with results for the starting income model.

Two variables (*SOUTH*2 and *URBAN*) were included in the 1985 income model to explain possible differences in income attributable to locational labor market conditions. *SOUTH*2, which indicated whether the 1985 job was located in one of thirteen southern states, was insignificant. A similar result was obtained in the starting income model. The second locational variable, *URBAN*, was significant. Parameter estimates showed that those situated in urban areas (large, medium, or small cities) earned expected mean incomes $3,332 higher than those in nonurban areas (outside a city or village, or on a farm or ranch). People tend to migrate toward places of employment that maximize returns to their investments in human capital. Because urban employment opportunities may offer greater financial returns, urban residence tends to be associated with higher income earnings. However, the real buying power of incomes between urban and rural residences may be nearly equivalent because of higher costs of living in urban areas.

Consistent with the first income model, the fringe benefit variable *PRFT* (profit sharing) was found to be significant. Those who participated in profit-sharing plans earned incomes $2,561 higher than those who did not. This income premium may be attributable to forces acting on both sides of the labor market. On the demand side, profit-sharing plans tend to be offered by larger and perhaps more progressive and profitable firms. Part of the higher earnings of such firms may be passed on to employees through both higher wages and profit sharing. On the supply side, aggressive individuals seeking to maximize incomes may be attracted to positions that offer profit sharing. If profit sharing is linked to employee performance, then such positions would tend to attract performance-oriented employees.

The provision of housing benefits (*HSG*2) did not have a statistically significant impact on 1985 incomes. This finding was consistent with results obtained in the starting income model.

Although parameter estimates suggested that women earned lower incomes than men during 1985, the difference was not statistically signif-

icant. Thus, gender-related differences in starting incomes appeared to decline with increased labor market experience. Effects of the *INC*1 variable, however, implied that males maintained a 1985 income advantage of at least $976 (0.563 × $1,733) over females.

Marital status was a significant determinant of 1985 income. Parameter estimates showed that married respondents earned an expected $2,421 more than those not married. Perhaps married individuals can better maximize their human capital investments because of the financial and emotional support provided by the spouse. Also, employers may perceive married employees to be more responsible and hence better investment risks.

In contrast to the starting income model, respondents' assessments of the need for particular skills for career improvement were found to contribute significantly to explaining the variation in 1985 incomes. Parameter estimates showed that those who ranked *ORAL* as much needed or essential had $4,279 higher mean 1985 incomes than those who ranked such skills as not or somewhat needed. The result reinforces the hypothesis that the use of oral communication skills tend to be associated with supervisory, managerial, or entrepreneurial level positions wherein financial compensations are higher (Broder and Houston).

In comparison, respondents who ranked a technical skill (*TECHNICAL*) as much needed or essential earned $5,386 less than those who ranked it as not or somewhat needed. This result, which was significant, confirms expectations that careers built on narrowly defined technical skills tend to be associated with lower incomes.

Implications

The labor market for graduates from colleges of agriculture is characterized by change and uncertainty. Because labor market information tends to be imperfect, employers and employees engage in a search process. The purpose of this study has been to better understand this search process by determining how individual characteristics, education, and occupational experiences influence the earnings of graduates from colleges of agriculture. This study concentrated particularly on changes in salary determinants that occur over the course of a person's career. The remainder of the discussion focuses on the implications for agricultural programs and for individual's careers.

Agricultural Curricula

Although recruitment of new students receives much attention from college administrators (Connor), retention of existing students represents an equally important dimension of addressing declining agricultural enrollments. Questionnaire results showed that fully one-fifth of the respondents either transferred to programs outside of agriculture or failed to obtain the bachelor's degree. Efforts to retain even a portion of these students may be more successful and cost effective than attempts to attract the same number of students from a diverse pool of incoming high school graduates and students enrolled in other programs.

As further evidence in support of retention programs in colleges of agriculture, the empirical results failed to identify significant salary differences attributable to the choice of major (agriculture, forestry, or other programs). In particular, one-time agricultural majors did not appear to enhance their future earnings by transferring to other colleges.

Recent articles about educational programs at land grant and other agricultural colleges have emphasized the need to broaden agricultural curricula (Schuh, Litzenberg and Schneider, Connor). The empirical results reported herein substantiate the proposition that colleges should provide broad-based training that maximizes individual adaptability to changing labor market conditions. Higher incomes for 1985 were associated with those who regarded oral communication skills as essential to their careers, while lower incomes were associated with those who rated a technical skill as essential to their careers. The results should not be interpreted superficially to suggest that the teaching of technical skills be eliminated from agricultural programs. Rather, the results reinforce the need to integrate the development of interpersonal skills into the college curriculum. Training in oral, written, and interpersonal skills need not be relegated to other departments but should be built into disciplinary course work and related extracurricular activities.

This study found that the salary premiums associated with advanced education tended to subside with career maturation. These findings suggest that curriculum design and educational reform may be of greatest benefit to graduates early in their careers and may have less influence on graduates later in their careers. Thus, colleges of agriculture should be sensitive to the dynamics of labor market information and em-

phasize curriculum reforms having swift and certain benefits in the labor market.

Career Strategies

This study found that educational achievement was a significant determinant of income on the first job but tended to diminish in importance on later jobs. From a benefit-cost perspective, the decision to pursue formal education at any level must rest ultimately on tradeoffs between financial goals, other personal objectives, and opportunity costs associated with enrollment in the educational program (Broder and Deprey). Given that personal emphasis on pay differs across individuals, the importance of both monetary and nonmonetary career objectives must be recognized. Indeed, the notion of personal benefit-cost assessment applies to virtually any decision over which individuals have some control. To take a job with a profit-sharing plan, for instance, an individual may have to bear the opportunity cost of forgoing a different position in a more desirable location. This study makes no pretense of offering advice on how individuals should weigh the intrapersonal tradeoffs associated with human capital investment decisions.

Because inherent personal characteristics may affect an employee's mobility, demographic variables were identified as potential determinants of earnings. This study found gender to be a significant determinant of starting salaries, though not of later earnings. Given this trend, the gender-wage differential appeared to lessen over time. This declining differential was attributed to the emergence of more reliable market information on the marginal value product of female workers. Thus, the results provide an encouraging outlook for women considering post-college careers in agriculture.

Starting incomes were found to have a positive and significant impact on later-year earnings while school-related attributes tended to diminish with time. Similarly, immediate job experience was a more important income determinant than was experience on previous jobs. These findings suggest the value of market information tends to deteriorate or have a limited shelf life over time as new information on job performance becomes available. The obvious and perhaps predictable implication is that employees striving for financial success cannot "rest on their laurels." As careers mature, remuneration based on observed job performance can outweigh either early successes or failures.

The Effects of State Farm Relief Legislation on Private Lenders and Borrowers: The Experience of the 1930s

Randal R. Rucker

The effects on private lenders and borrowers of farm relief programs that alter the enforceability of debt contracts are investigated. Evidence from the 1930s indicates that state relief legislation that altered debt contracts to the detriment of lenders substantially reduced the supply of loans and had different effects on different types of private lenders. This past experience suggests that, although such measures as moratoria on farm foreclosures and the recently enacted Chapter 12 bankruptcy law may provide relief for some farmers, they may also result in substantial reductions in the supply of agricultural credit.

Key words: agricultural credit, bankruptcy law, farm policy, foreclosure moratoria.

A significant number of farmers have suffered severe financial stress in recent years (Boehlje, Thamodaran, and Barkema; Melichar). Predicting the likely impacts of the various proposals for alleviating these problems is difficult. The most common approach is to estimate the effects of different policy options using simulation models (Barry 1986; Boehlje, Thamodaran, and Barkema; Pederson et al.). An alternative approach is to look to the past for similar experiences in order to obtain useful insights about the present situation. Changes in agricultural financial markets over time preclude using historic information to make precise predictions about contemporary issues. However, the past can provide useful insights into the general magnitudes and directions of the responses to current policy options.

The historical approach is used in this paper to examine the effects of government-imposed measures that alter the enforceability of agricultural debt contracts. Recent examples of such measures include the Chapter 12 bankruptcy law that went into effect in 1986 and moratoria on farm foreclosures like those enacted in Iowa in 1985 and considered by legislators in other farm states. Such measures may provide short-term relief to some farmers. However, they also impose costs on lenders and may reduce the supply of credit to the agricultural sector.[1]

The period studied in this paper is the 1930s, the most recent period (prior to the early 1980s) of severe agricultural distress in the United States. Included among the programs instituted in the 1930s to provide relief for the farm sector were state-legislated moratoria on farm foreclosures. This paper examines the effects of these moratoria and other types of state relief programs on the supply of farm loans in the 1930s.

The use of data from the past to glean insights into current agricultural finance problems has not been widely employed. Shepard and Collins used time-series data to investigate the determinants of aggregate farm bankruptcy rates. They included a general agricultural policy variable (government support payments as a proportion of all farm revenues) as an explanatory variable

[1] Evidence consistent with such a response to the Chapter 12 bankruptcy law was cited shortly after its enactment. See "Farm Bankruptcy Law Halts Some Loans and Stirs Fears About Farmers' Credit," *The Wall Street Journal,* 19 Jan. 1987.

in their empirical analysis but did not investigate the effects of particular programs on bankruptcy rates. Rucker and Alston used data from the period 1929–40 to investigate the effects of government programs on rates of farm failure during the 1930s; they found that state-legislated moratoria did reduce farm failure rates. Alston (1984) used state-level cross-sectional data to investigate the causes and consequences of state-legislated moratoria during the 1930s. His reduced-form estimates indicated that moratoria led to significant reductions in the quantity of private loans. The present paper extends Alston's work by estimating the structural and interregional effects of state relief legislation on different types of private lenders.

This paper is organized as follows. Mortgage foreclosure procedures and state relief legislation passed during the early 1930s are described in the next section; then, a system of demand and supply equations for loans from government and private lenders is presented, the effects of relief legislation are predicted, the empirical specification is described, and the results of the empirical analysis are reported. The concluding section considers the implications of the results for recent farm problems.

The Mortgage Foreclosure Process and State Relief Legislation in the 1930s

If an individual borrower became delinquent on his mortgage payments, the lender decided whether to grant the borrower an extension or to foreclose on the mortgage. If the lender chose to foreclose, then he initiated the process for selling the property.[2] The sale was conducted through an auction in which any interested parties, including the original lender, could bid on the property. If the winning bid exceeded the amount due in principal and interest on the first mortgage, then the lender received payment and the remaining funds were divided among other lenders holding liens on the property. Any funds remaining went to the borrower. In some states if the winning bid was less than the debt owed on the first mortgage, the lender could sue for a deficiency judgment for the difference.

After the auction, the borrower often was granted a redemption period. If, during this period, he was able to pay off the mortgage plus any accrued costs, he could recover title to the property. If the borrower (or a junior lender) did not pay off the mortgage during the redemption period, then the title to the property was transferred to the high bidder at the auction.

Prior to the Great Depression, there were isolated instances of states passing legislation during periods of depressed earnings to provide relief to debtors from their contractual loan obligations (Alston 1984, Friedman, Woodruff). The experience of the 1930s was unique, however, in two respects. First, it was unique in its magnitude: more than half the states enacted relief legislation. Second, the constitutionality of this type of relief legislation was upheld by the U.S. Supreme Court for the first time.[3]

State-legislated relief for debtors during the 1930s generally took three forms: (*a*) moratoria on foreclosures, (*b*) extension of the redemption period, and (*c*) limitation (or abolishment) of deficiency judgments. Legislation of the first type generally gave the courts discretionary power to postpone foreclosure proceedings over a specified period. Postponement periods varied in duration across states and sometimes were extended when the initial legislation expired. Foreclosures were not completely prohibited under these laws. Borrowers were usually required to make certain payments to lenders—interest, taxes, and court-specified rents.[4] Failure to make these payments could lead to foreclosure.

The second type of relief legislation temporarily increased the length of redemption periods. This type of legislation imposed costs on lenders by delaying the time at which clear title could be obtained by the new owner. Although the borrower was required to make court-specified payments to the lender during this redemption period, these payments were less than payments received under normal circumstances (Woodruff, pp. 114–15). In addition, under these arrangements borrowers were inclined to neglect the property and may have been willfully destructive in some instances.

The third type of relief legislation restricted creditors' rights to deficiency judgments. In some states, e.g., North Dakota, such judgments were

[2] Foreclosure could be accomplished either by advertisement (power of sale) or by court action (judicial foreclosure). The procedure for initiating a foreclosure differed somewhat depending on the foreclosure method chosen. Woodruff (appendix A) indicates that during the 1930s most states enacted legislation requiring foreclosure by action.

[3] The landmark case on relief legislation was *Home Building and Loan Association* v. *Blaisdell et al.*, in which the constitutionality of relief legislation enacted in Minnesota was upheld.

[4] Rents paid under these arrangements tended to be less than those paid by tenants renting under normal circumstances (Woodruff, pp. 114–15).

abolished. In others, the dollar value of deficiency judgments was limited, often by setting a minimum auction price for the property.

Supply and Demand for Farm Mortgage Loans

If the three types of relief legislation described above were viewed by lenders as an attenuation of valued rights in future mortgage contracts, then decreases in the supply of loans are expected following the enactment of such legislation. This and related issues involving differences among lenders and across regions in the effects of relief legislation are investigated using the following model of the supply and demand for farm mortgage loans.

Supply of Farm Mortgage Loans

$$Q^s_{GOV} = \alpha_0 + \overset{(+)}{\alpha_1}FDRDUM + \overset{(0)}{\alpha_2}STRESS + \overset{(+)}{\alpha_3}(FDRDUM{*}STRESS) + \epsilon_1 \tag{1}$$

$$Q^s_{INDIV} = \beta_0 + \overset{(-)}{\beta_1}RLFLEG + \overset{(+)}{\beta_2}INTINDIV + \overset{(-)}{\beta_3}INTALT + \overset{(+)}{\beta_4}SZINDIV + \overset{(-)}{\beta_5}DEBT/VALUE + \epsilon_2 \tag{2}$$

$$Q^s_{BANK} = \gamma_0 + \overset{(-)}{\gamma_1}RLFLEG + \overset{(+)}{\gamma_2}INTBANK + \overset{(-)}{\gamma_3}INTALT + \overset{(+)}{\gamma_4}SZBANK + \overset{(-)}{\gamma_5}DEBT/VALUE + \epsilon_3 \tag{3}$$

$$Q^s_{INSUR} = \delta_0 + \overset{(-)}{\delta_1}RLFLEG + \overset{(+)}{\delta_2}INTINSUR + \overset{(-)}{\delta_3}INTALT + \overset{(+)}{\delta_4}SZINSUR + \overset{(-)}{\delta_5}DEBT/VALUE + \epsilon_4, \tag{4}$$

where Q^s_{GOV}, Q^s_{INDIV}, Q^s_{BANK}, and Q^s_{INSUR} are the quantities (dollar value) of farm mortgage loans supplied by government lenders, individuals, banks, and insurance companies in state i in year t. The other variables are defined in table 1.

Predicted signs for the coefficients of the explanatory variables are indicated in parentheses above the coefficients. The hypothesized supply of government loans is a function of whether President Franklin D. Roosevelt was in office (*FDRDUM*) and the level of financial stress (*STRESS*), *FDRDUM* has a positive coefficient, reflecting the increase in federal lending following Roosevelt's election in 1932. Prior to 1933, the mandate of federal credit agencies was to supply loans in regions where private funds were not readily available.[5] If the activities of these agencies did not vary with the degree of farm distress prior to 1933, the coefficient on *STRESS* is zero. After 1932, a stated objective of federal lending agencies was to provide funds to those farmers suffering the most; thus, the coefficient on the interactive variable (*FDRDUM*STRESS*) is positive.

In the three private supply equations, (2)–(4), the coefficient on the relief legislation variable (*RLFLEG*) is negative, indicating that private lenders will decrease their activities as mortgage contracts are altered to their detriment. The predicted coefficients on the respective own-interest rate variables (*INTINDIV, INTBANK,* and *INTINSUR*) are positive, reflecting upward sloping loan supply curves. An increase in the rate of return on alternative investments will reduce the supply of farm mortgage loans; hence the coefficients on *INTALT* are negative. If there are fixed costs associated with issuing loans, then an increase in average loan size will reduce transaction costs (per dollar of loans issued), thereby increasing the supply of loans. Hence, positive coefficients are predicted on *SZINDIV,*

[5] Federal lending agencies include the federal land banks and the Land Bank Commissioner. For a detailed account of the activities of these agencies during the 1930s and the changes that were instituted under Roosevelt, see Horton, Larsen, and Wall.

SZBANK, and *SZINSUR*. An increase in farm leverage is predicted to decrease the supply of loans from private lenders; hence, the coefficients on *DEBT/VALUE* are negative.

Demand for Farm Mortgage Loans

The following equations,

$$(5) \qquad Q^d_{GOV} = Q^s_{GOV} \text{ if } INTGOV < INTPRIV$$
$$= 0 \text{ otherwise}$$

$$(6) \qquad Q^d_{PRIV} = \tau_0 + \underset{(\pm)}{\tau_1 RLFLEG} + \underset{(-)}{\tau_2 INTPRIV} + \underset{(+)}{\tau_3 DEBT/EEARN} + \underset{(-)}{\tau_4 Q_{sGOV}} + \epsilon_6$$

$$(7) \qquad Q^d_{INDIV} = \phi_0 + \underset{(-)}{\phi_1 INTINDIV} + \underset{(+)}{\phi_2 INTBANK} + \underset{(+)}{\phi_3 INTINSUR} + \underset{(+)}{\phi_4 Q^d_{PRIV}} + \epsilon_7$$

$$(8) \qquad Q^d_{BANK} = \theta_0 + \underset{(+)}{\theta_1 INTINDIV} + \underset{(-)}{\theta_2 INTBANK} + \underset{(+)}{\theta_3 INTINSUR} + \underset{(+)}{\theta_4 Q^d_{PRIV}} + \epsilon_8$$

$$(9) \qquad Q^d_{INSUR} = \Omega_0 + \underset{(+)}{\Omega_1 INTINDIV} + \underset{(+)}{\Omega_2 INTBANK} + \underset{(-)}{\Omega_3 INTINSUR} + \underset{(+)}{\Omega_4 Q^d_{PRIV}} + \epsilon_9,$$

where Q^d_{GOV}, Q^d_{INDIV}, Q^d_{BANK}, Q^d_{INSUR}, and Q^d_{PRIV} are the quantities of farm mortgage loans demanded from government lenders, individuals, banks, insurance companies, and private lenders, respectively, in state *i* in year *t*. The other variables are defined in table 1.

In the demand for government loans equation (5), borrowers are assumed to demand as many funds as federal credit agencies will provide, as long as the interest rate on government loans is less than the interest rate on private loans [which was generally the case following the advent of Roosevelt's New Deal programs (USDA 1938, 1939)].

Borrowers' demand for loans from private lenders is modeled as a two-step process. In the first step [equation (6)] farmers decide how much to borrow from private lenders as a group. This decision is based on average interest rates on loans available from private lenders (as well as other factors discussed below). In the second step, farmers decide how to allocate their borrowing among the three types of private lenders. This decision is based on the relative interest rates available from the three types of lenders.[6]

In the first-step private demand equation (6), the predicted coefficient of the relief legislation variable is uncertain. On the one hand, the relief legislation of the early 1930s increased the attractiveness of mortgage loans to borrowers. On

[6] An alternative "one-step" model of demand is to specify the demand for loans from each type of lender as a function of relief legislation, the ratio of debt to discounted expected future income, the supply of government loans, and the interest rates of all three lenders. The two-step approach is used because it provides more precise coefficient estimates. The choice between these two specifications has no effect on the empirical estimates of the impact of state relief legislation on the supply of loans.

Table 1. Definitions of Variables

FDRDUM—zero-one dummy variable to indicate whether President Franklin D. Roosevelt was in office.
STRESS—extent of farm financial stress in state *i* as of year *t*.
*FDRDUM**STRESS*—interactive term between *FDRDUM* and *STRESS*.
RLFLEG—zero-one dummy variable to indicate whether relief legislation was in effect in state *i* in year *t*.
INTINDIV, *INTBANK*, and *INTINSUR*—average rates of interest charged on farm-mortgage loans recorded in state *i* in year *t* by individuals, banks, and insurance companies.
INTALT—interest rate available on alternative investments in year *t*.
SZINDIV, *SZBANK*, and *SZINSUR*—average size (dollar value) of loans issued in state *i* in year *t* by individuals, banks, and insurance companies.
DEBT/VALUE—ratio of total farm debt to the value of farm assets (land and buildings) in state *i* in year *t*.
INTGOV and *INTPRIV*—average rates of interest charged on farm mortgage loans recorded in state *i* in year *t* by federal lenders and by private lenders as a whole.
DEBT/EEARN—ratio of total farm debt to the discounted value of expected future net farm income in state *i* in year *t*.

the other hand, borrowers observed that state governments now could change the terms of existing contracts between private parties. If borrowers feared that future relief legislation might be designed to benefit lenders rather than borrowers, then the uncertainty would increase concerning the security of their property rights in future mortgage contracts. This would lead to a reduction in loan demand. The relative magnitudes of these offsetting effects is an empirical question.

An increase in the average rate of interest on private loans will lead to a reduction in the quantity of private loans demanded; hence, the coefficient on *INTPRIV* is negative. An increase in the level of debt relative to the present value of the expected future flow of income will decrease the demand for loanable funds, implying that the coefficient on *DEBT/EEARN* is negative.

The coefficient on Q^s_{GOV} in equation (6) is bounded by 0 and -1, with the actual value determined by the allocation of government loans among private borrowers. A value of zero indicates that all the low interest rate government loans were allocated to borrowers not willing to pay the market-clearing interest rate. At the other extreme, if all government loans were allocated to borrowers willing to borrow at market interest rates, then the demand for private loans would shift to the left by the amount of the government loans; that is, the value of the coefficient on Q^s_{GOV} would be -1. For intermediate cases this coefficient is between 0 and -1.[7]

In the second-step demand equations, (7)–(9), an increase in the interest rate on loans from a particular lender will decrease the quantity of loans demanded from that lender, and the coefficients ϕ_1, θ_2, and Ω_3 will be negative. If loans from different types of lenders are substitutes, an increase in the rate charged by one lender will increase the demand for loans from other lenders and the coefficients ϕ_2, ϕ_3, θ_1, θ_3, Ω_1, and Ω_2 will be positive. An increase in the total demand for private loans will result in increased demand for loans from each type of lender; hence, the coefficients on Q^d_{PRIV} in equations (7)–(9) are positive.

Additional Issues

The model of supply and demand for agricultural loans presented above allows the investigation of whether relief legislation had different effects on different types of private lenders and in different regions. The lender effects are indicated by differences in the estimated coefficients on *RLFLEG* in equations (2)–(4). To illustrate, relief legislation might have affected insurance companies less than individuals and banks for two reasons.

First, borrowers are more likely to borrow from a lender if they believe that lender is less likely to foreclose when loan problems occur. Lenders, therefore, have an interest in establishing "goodwill capital," perhaps by granting extensions to farmers experiencing loan delinquences caused by factors beyond their control. The costs to lenders of granting extensions rather than foreclosing and reselling the property differ among lenders. Insurance companies, unlike most local banks and individual lenders, normally had portfolios that included mortgage loans from several regions (Woodruff, p. 49). Because lending problems varied among regions during the 1930s, delinquent loans in a particular area would have a smaller (proportional) effect on insurance companies than other lenders. In addition, insurance companies were better diversified than other lenders, in that a smaller portion of their portfolios was allocated to mortgage loans. If insurance companies did have to turn to capital markets to compensate for delinquent payments, their cost of funds likely was lower than for individuals and local banks. Thus, insurance companies were more likely than other lenders to grant extensions to delinquent borrowers. In turn, they likely were less affected by relief legislation than other lenders.[8]

Second, the regional orientation of insurance companies and the long distances between central offices and borrowers' locations increased the cost of monitoring borrower performance. As a result, insurance companies tended to make larger, lower-risk loans (Alston forthcoming, Woodruff). Because lower-risk borrowers were less likely to experience loan delinquencies, foreclosure rates on insurance company mortgages should have been lower, and the costs imposed on them by relief legislation would be lower than for other lenders.

Another issue concerns differences in the impacts of relief legislation across regions that may

[7] See Rucker for further discussion of this issue.

[8] Woodruff commented several times on the insurance companies' efforts to be lenient toward borrowers during the early 1930s. Alston speculated that "individuals—and perhaps local banks—being less diversified and facing a more severe income constraint than insurance companies and federal financial institutions had more of an incentive to foreclose" (1984, p. 451).

have resulted from interstate differences in the provisions and enforcement of the legislation. Because the laws differed in numerous dimensions and because court enforcement was not uniform across states, the severity of the various states' legislation cannot be quantified. However, a subjective measure of the relative severity of legislation was recently provided by Woodruff. He suggested that from the perspective of banks and individual lenders, the most restrictive relief legislation was enacted in the two Dakotas, Minnesota, and Wisconsin.[9] Thus, the impacts of relief legislation were likely greater in these states than elsewhere.

Empirical Specification

The system of equations (1)–(9) is estimated using pooled time-series cross-sectional data for the period 1930–35. The estimation procedure uses the dummy variable model described by Judge et al. (pp. 478–88) in a simultaneous equations setting using two-stage least squares. Cross-sectional units are distinguished by including zero-one state dummy variables.

Insurance companies did not issue farm loans in all states in the 1930s. Because these companies were an important source of loanable funds in many states and because the impact of relief legislation on these companies is of interest, the data set is restricted to the thirty-two states in which data for interest rates on insurance company loans are available for the years 1930–35.[10] Of these states, twenty-two legislated one or more of the three types of relief legislation discussed above (see Rucker, table 1, for specifics).

Although annual data on the loan quantities (dollar value) of federal lending agencies (*QGOV*) are available (U.S. Congress 1931–33; Farm Credit Administration 1934–36; Horton, Larsen, and Wall, table 78, p. 245), no data on the annual quantity of loans issued by private lenders were published. Estimates of these quantities are constructed using data on federal loan quantities and on the percentage of loans issued by federal and private lenders (USDA 1940b).

In the government supply equation, *FDRDUM* is a zero-one dummy variable that is included to measure the impacts of Roosevelt's programs on the supply of federal credit. This variable is assigned a value of one in 1934 and 1935, and a value of zero otherwise.[11] Two measures of financial stress are used. *STRESS*1 is the simple average of earnings in years t-1 and t-2 (USDA Jan. 1946). A reduction in this variable measures an increase in "short-run" stress, or cash shortfalls. To control for interstate differences in the levels of state farm earnings, earnings in state i in year t are divided by earnings in state i during a base period (the average of earnings in 1924 and 1925). *STRESS*2 is a simple average of the ratio of an index of total farm debt (Horton, Larsen, and Wall) to the value of land and buildings (Regan and Johnson) in years t-1 and t-2. An increase in this variable indicates greater "long-run" stress, or leverage problems.

The variable *RLFLEG* is assigned a value of one if any of the three types of state relief legislation were in effect in a given state in a given year. Alston's analysis was limited to the effects of legislation that postponed foreclosures (moratoria). The discussion above of the different types of state relief legislation suggests that the effects of legislation extending redemption periods and limiting deficiency judgments may also be important. The estimation of several specifications designed to measure separately the effects of these different types of relief legislation suggest that the data are not capable of distinguishing their separate effects. This result is attributed to the fact that states often enacted two or three types of relief legislation at (roughly) the same time (U.S. Congress, April 1936; USDA, June 1934).

Annual data on interest rates and average loan sizes are obtained directly from USDA reports (1938, 1939, 1940a). The variable used to measure leverage (*DEBT/VALUE*) is the ratio of an index of farm mortgage debt to an index of land values. The proxy used for the rate of return on alternative investments in year t (*INTALT*) is the rate of interest on commercial paper in year t (Federal Reserve bulletins).

In the first-step demand equation, the proxy used for the discounted value of expected earnings (*EEARN*) is the value of farm land and buildings in state i in year t. Thus, the same proxy is used for *DEBT/EEARN* in this equa-

[9] Letter from Archibald Woodruff, dated 12 Aug. 1982, to Lee Alston and telephone conversation between Alston and Woodruff.

[10] There are a few instances in which data on interest rates on insurance loans are not available for a particular year and in which the average interest rate on government loans exceeded the interest rate on loans from one of the three classes of private lenders. To maintain consistency with the system described by equations (1)–(9), these observations are deleted from the data set.

[11] Preliminary analysis indicated that the specification of the government supply equation was improved by assigning *FDRDUM* a value of one for 1934 and 1935 rather than for 1933–35. This suggests that it was a year after Roosevelt took office before his programs had measurable effects.

tion as for *DEBT/VALUE* in the supply equations.

Estimation Results

Preliminary regression results for the supply equations (1)–(4) suggested that interest rates on loans of insurance companies might be exogenous. Because insurance companies tended to operate on a larger scale than other private lenders and at a national rather than a local level (Woodruff, p. 49), interest rates on their loans may have been exogenous to borrowers in a particular state. A Wu-Hausman test failed to reject the null hypothesis that these interest rates were predetermined.[12] Given this result, the interest rate on loans by insurance companies is not affected by shifts in the state-level demand for loans from insurance companies but may be influenced by relief legislation, interest rates on alternative investments, and so forth. The system of equations (1)–(9), therefore, is estimated by replacing equation (4) with an equation in which the interest rate on insurance company loans is regressed on the variables *RLFLEG, INTALT, DEBT/VALUE*, and *SZINSUR*. Extension of the logic presented in the discussion of the supply equations suggests that the estimated coefficients on the first three of these variables are positive and that the coefficient on *SZINSUR* is negative. Estimation results are displayed in table 2.[13]

In the government supply equation, the estimated coefficient on *FDRDUM* indicates a statistically significant increase in new loans issued by government credit agencies following 1933. The statistically insignificant coefficient on the first measure of stress, *STRESS*1, suggests that before 1934 federal credit agencies did not respond to differences in recent earnings levels, while the coefficient on *STRESS*2 indicates a significant increase in government loans in response to adverse leverage experience. The coefficient on the interactive variable *FDRDUM*STRESS*1 indicates a highly significant change after 1933 in the responsiveness of federal credit agencies to shortfalls in recent earnings. The coefficient on *FDRDUM*STRESS*2 suggests a marginally significant change in responsiveness to differences in leverage experience (p-value = .15).

[12] The t-ratio from this test is equal to .85. See Thurman for discussion of the use of this statistical test.

[13] Data from all thirty-two states in the sample are used to obtain the coefficient estimates in table 2.

In the supply equations for individual and bank lenders, the coefficients on *INTALT* and *DEBT/VALUE* all have the predicted negative signs, while the coefficients on loan size and own-interest rate have the predicted positive signs. The coefficients on the relief legislation dummy variables are negative and statistically significant in both equations. The estimated coefficients on the *RLFLEG* variables indicate that (*ceteris paribus*) state relief legislation resulted in reductions in the annual supply of loans from individual lenders and banks of $2,512,000 and $1,867,000, respectively. These amounts represent 31% and 35% of the average annual quantity of mortgage loans issued by individuals and banks. These results suggest that relief legislation resulted in substantial reductions in the supply of agricultural credit from banks and individual lenders.

In the equation for insurance company interest rates, as predicted, the coefficients on the interest rate on alternative investments (*INTALT*) and leverage (*DEBT/VALUE*) are positive and significant. The coefficient on the relief legislation dummy variable is positive but not significant.

In the first-step demand equation in table 2, the estimated coefficients on *INTPRIV* and *DEBT/EEARN* have the predicted negative signs. The estimated coefficient on Q^{*}_{GOV} is significantly less than zero and greater than -1. Apparently, some of the low interest government loans were allocated to borrowers willing to borrow at market interest rates, i.e., federal loans "crowded out" some privately supplied loans. A coefficient significantly greater than -1 suggests that a portion of government loans was granted to borrowers who were not willing to pay the market-clearing interest rates that would have prevailed on private loans in the absence of government credit. The estimated coefficient on *RLFLEG* is negative and statistically significant. This result suggests that the demand-reducing effects of the 1930s legislation (from increased uncertainty concerning property rights in private loan agreements) outweighed any demand-increasing effects (from the pro-debtor nature of the legislation).

In the second-step demand equations (whose estimated coefficients are not shown in table 2), only two of the nine estimated coefficients on the interest rate variables are significantly different from zero. The inability to sort out the individual effects of the three interest rate variables is attributed to the high degree of collinearity among them (the three pairwise correla-

$R^2 = .8721$

Note: t-ratios are in parentheses.

tion coefficients ranged from .6 to .8).

The system whose estimates are presented in table 2 constrains slope coefficients to be equal across all states. This constraint is relaxed, and interregional differences in the impacts of state relief legislation are investigated by estimating different systems of equations for different regions. Table 3 contains the coefficient estimates and t-ratios for the *RLFLEG* variables for each of the seven regions in which insurance companies were active.

The first two columns in table 3 show the estimated effects of relief legislation on the supply of loans from individuals and banks. Ten out of fourteen of the coefficients in these columns are negative, with seven of them negative and statistically significant at a 10% level. The third column indicates that in only one of the seven regions did relief legislation have a positive and statistically significant impact on the interest rate on loans from insurance companies.

In all of the seven regions, the estimated coefficient on the government supply variable in the first-step demand equations (not shown in table 3) is significantly greater than -1, implying (as did the coefficient in table 2) that a portion of the government credit was allocated to borrowers not willing to borrow from private lenders. The coefficient on this government supply variable is significantly less than zero in three regions (West North Central, Mountain, and Pacific) indicating that, in those regions, increases in government-supplied credit in the early 1930s "crowded out" private loans. Also, the estimated coefficient on the relief legislation variable in the first-step demand equation is negative in six of the seven regions but is statistically significant in only two regions (Pacific and East South Central).

Tables 2 and 3 provide information concerning the magnitude and significance of shifts in the supply curves of private lenders resulting from the relief legislation in various states. Another useful measure is the impact of these laws on the market shares of private lenders. The market share of federal credit agencies increased during the 1930s because of the expanded credit programs instituted by Roosevelt and because of the reduced lending by private creditors resulting from state relief legislation. Estimates of the effects of state relief legislation on the percentage of loans issued by individuals, banks, and in-

Note: Individual and bank loans were made in all states. Those states in each region in which insurance companies also operated are,
East North Central: Ohio, Indiana, Illinois, Michigan, and Wisconsin.
West North Central: Minnesota, Iowa, Missouri, North Dakota, South Dakota, Nebraska, and Kansas.
South Atlantic: Maryland, Virginia, North Carolina, South Carolina, and Georgia.
East South Central: Kentucky, Tennessee, Alabama, and Mississippi.
West South Central: Arkansas, Louisiana, Oklahoma, and Texas.
Mountain: Montana, Idaho, Colorado, and Arizona.
Pacific: Washington, Oregon, and California.
Of these states, relief legislation was passed in Ohio, Illinois, Michigan, Wisconsin, Minnesota, Iowa, North Dakota, South Dakota, Nebraska, Kansas, North Carolina, South Carolina, Alabama, Mississippi, Louisiana, Oklahoma, Texas, Montana, Idaho, Arizona, and California.

[a] Columns 1, 2: significantly negative at the 10% level (one-tailed test). Column 3: significantly positive at the 10% level (one-tailed test).

[b] t-ratios are in parentheses.

surance companies are presented in table 4. These estimates are the reduced-form coefficient estimates from a system of structural equations like (1)–(9) in which quantities of loans supplied by and demanded from different lenders have been replaced with percentages of loans supplied by and demanded from those lenders.

The rows of table 4 contain the estimated coefficients on the *RLFLEG* variable for each of the seven regions. The estimated effect of relief legislation on the percentage of loans issued by private lenders (shown in the 4th column) is negative in all the regions. Across the seven regions, the average reduction in the share of private lenders (or the increase in the share of federal credit agencies) resulting from state relief legislation is 20.17%. The average reductions in the shares of individuals, banks, and insurance companies are 14.11%, 5.87%, and .20%, respectively.

The prediction that banks and individual lenders were affected more than insurance companies by the state relief legislation of the 1930s is supported by the empirical estimates. In tables 2 and 3, the supply of credit from banks and individual lenders generally decreases, while the rate of interest on insurance company loans does not increase significantly as a result of relief legislation. Although the estimates reported in table 4 are reduced-form estimates, their ranking is consistent with the structural hypothesis that insurance companies were affected less by relief legislation than banks or individuals.

Woodruff observed that, from the perspective of banks and individual lenders, states in the East North Central and West North Central regions (North and South Dakota, Minnesota, and Wisconsin) passed the most restrictive relief legislation. The prediction that lending by banks and individual lenders in these states should experience the greatest reduction receives mixed support from the estimates reported in tables 3 and 4. In table 3 the reported coefficients indicate that the supply of loans from both individuals and banks in the West North Central region fell significantly. In the East North Central region, only the reduction in the supply of loans from individuals is significant. In table 4, the estimated reduction in the percentage of loans issued by banks and individual lenders is the sum

Table 4. Effects of Relief Legislation on Market Shares of Private Mortgage Loans

Region	$\frac{\partial\%INDIV}{\partial RLFLEG}$	$\frac{\partial\%BANK}{\partial RLFLEG}$	$\frac{\partial\%INSUR}{\partial RLFLEG}$	$\frac{\partial\%PRIV^{a}}{\partial RLFLEG}$

of the entries in the first two columns. These estimated reductions are substantially greater in the East North Central and West North Central regions (−35.82 and −32.71) than in the other regions.

Concluding Comments

Government programs often have effects other than those predicted by their proponents. This appears to be true for state farm relief legislation enacted in the 1930s. Although Rucker and Alston indicate that this legislation had the desired effect of reducing farm failure rates, the present paper suggests that this legislation also resulted in significant reductions in the supply of loans from certain types of private lenders. Clearly, the structure of agriculture and of farm credit markets has changed since the 1930s. Farms are now larger and more highly leveraged, individual lenders and banks hold a smaller share of the outstanding debt, insurance companies lend almost exclusively to large commercial farms, the role of the Farm Credit System is larger, and the Farmers Home Administration is a major presence.

Given these differences, what lessons are learned from the 1930s experience? Certainly, the incentives have not changed for private lenders to compare the attributes of alternative investments and to modify their portfolios in response to changes in the relative attractiveness of different investments. Therefore, a primary lesson from the 1930s is that government-imposed measures to make agricultural debt contracts less attractive to lenders will reduce the supply of credit from private lenders. If the current responsiveness of lenders to such measures is similar to their responsiveness in the 1930s, then these reductions in supply will be substantial. Indeed, easier access to capital markets suggests that the current response might be greater than in the 1930s.

Although individuals and banks now play a smaller role in agricultural credit markets than in the 1930s, at the margin, reductions in credit from private lenders will still impose costs on some borrowers. In the 1930s, the costs borne by borrowers from reduced supplies of private credit following the enactment of state relief legislation were limited because federal credit agencies were expanding rapidly and pursuing "easy credit" programs. Although the share of federally held credit is larger now than in the 1930s, federal credit agencies have come under pressure to improve the profitability of their operations and there has been considerable interest in reducing their role (Barry 1985). Federal lenders are therefore not likely to provide as soft a cushion for borrowers as they did in the 1930s.

The analysis in this paper yields two other interesting results about the farm credit experience of the 1930s. First, in some instances, federal credit programs "crowded out" private lenders by providing low interest loans to borrowers who

were willing to borrow at the market rates. Second, the empirical results suggest that the state relief legislation of the 1930s actually reduced the demand for farm credit because of increased uncertainty to borrowers concerning the sanctity of future private loan agreements. The resulting reduction in demand for loans from this effect appears to have outweighed any increased demand resulting from features of the 1930s legislation that were favorable to borrowers.

Utilization, Profitability, and the Adoption of Animal Draft Power in West Africa

William K. Jaeger and Peter J. Matlon

Farmers in West Africa's semi-arid tropics have been slow to adopt animal draft power to replace manual cultivation, defying the logic of conventional choice-of-technique analyses. This paper demonstrates that farmers can profitably adopt animal draft power when household characteristics and exogenous factors permit high utilization of animals and equipment. Empirical analysis of farm-level data indicates that low utilization is the key cause of low returns, and that a long learning period precedes achieving high utilization and benefits. Linear programming models are used to establish the importance of family size, access to land, and appropriate implements in achieving profitable adoption.

Key words: animal traction, learning curve, linear programming, semi-arid tropics, technology adoption, utilization.

Animal draft power presents a complex and important puzzle for agricultural development in the West African semi-arid tropics. Although animal traction has been promoted in most parts of the region since the beginning of the twentieth century, it is currently employed on less than 15% of total sown area (Spencer). Sustained adoption has occurred only in relatively limited geographic areas, such as the Sine Saloum region of Senegal, southern Mali, and southwestern Burkina Faso (Matlon). Elsewhere, initial adoption rates not only have been low, but early adopters have often abandoned the technique within three to five years (Sargent et al.). These patterns defy the logic of conventional choice-of-technique analyses. Although the West African semi-arid tropics are generally characterized as land abundant with seasonal labor shortages considered the primary production constraint (Norman, Newman, and Ouedraogo; Delgado and Ranade), farmers in most areas have not adopted a potentially labor-saving technique. This issue has generated considerable policy debate and a growing literature analyzing the principal adoption constraints.

Early studies examined factors limiting the supply of appropriate technologies and concluded that broad adoption was blocked by equipment inappropriately designed for African conditions, inadequate extension, and the absence of support services (Kline et al., Le Moigne). More recent field studies have shifted the debate to an examination of farm-level profitability and the demand for animal traction (Barrett et al., Lassiter, Delgado, Delgado and McIntire). The notable work by Delgado and McIntire concluded that oxen cultivation, in isolation from other components of improved technology, is not sufficiently profitable to compensate for the high opportunity cost of farm resources tied up in the technology. They used a conventional linear programming approach to examine farm-level demand for animal traction. Their model was synthesized from survey data from Burkina Faso (in a region where no animal traction was used) and Mali as well as from research station trials data from a variety of West African locations. Crawford and Lassiter, however, criticized that study (based on their own extensive field research in Burkina Faso) as having overestimated the labor costs of animal maintenance, for having underestimated supply-side constraints to traction adoption (extension, veterinary services, credit, equipment repair), and for using a single-period profit analysis to

model a dynamic adoption process.

In this paper we present new data from four regions of Burkina Faso which demonstrate that animal traction can generate competitive returns to labor and capital. We describe the conditions under which farmers can use animal traction profitably, showing that high utilization of animals and equipment is crucial for profitable adoption. And we analyze the principal factors, both exogenous and endogenous to farm households, that can limit potential utilization and profitability of various animal traction components or equipment sets.

Characteristics of the Farming Systems

The present study draws on farm-level crop production data from six villages in four regions of Burkina Faso for the 1981 and 1982 seasons. Each region is represented by a sample of fifty to sixty households selected by a stratified random sampling procedure to arrive at approximately equal numbers of farm units employing animal traction and manual tillage techniques. Complete sets of input-output data were collected for each plot through weekly or biweekly interviews during the respective growing seasons. The study sites were selected to span the three major agroclimatic zones of West Africa's semi-arid tropics. They represent the dry Sahelian zone, the intermediate Sudanian zone, and the relatively humid northern Guinean zone (table 1). Land was relatively abundant in both the Sahel and north Guinean zones. Within the intermediate Sudanian zone, two sites were included to represent relatively high and relatively low population densities.[1] The length of the growing season, the reliability of rainfall, and the quality of the soils all improve moving from north (Sahelian zone) to south (north Guinean zone).

These regional conditions suggest that the northern Guinean region has the highest technical potential for gains from mechanized plowing (long season, heavier soils, crops responsive to intensification) and weeding (long season and land abundance provide opportunities for use). A highly elastic demand for cotton, produced in quantity only in that region, reinforces this expectation. The land-abundant Sudanian zone has considerable potential for mechanized weeding, but the densely populated Sudanian zone appears to have only moderate potential for either mechanized operation. The Sahelian zone has the least potential for gains from plowing (light soils) or for weeding (very short season limits opportunities for use).[2]

This assessment of the regional variation in potential for adoption is underscored by a recent comparative survey of the agronomic, demographic, and market conditions under which mechanized plowing has proven to be appropriate in Sub-Saharan Africa. Pingali, Bigot, and

[1] Data for the land-scarce and land-abundant Sudanian zones are from Nedogo and Diapangou, respectively. Those surveys were conducted by Purdue University's SAFGRAD project. The Sahel data comes from two villages near Djibo and the northern Guinean sample from two villages near Boromo, both collected as part of ICRISAT's West Africa Village Studies. The SAFGRAD data is for 1982, the ICRISAT data is for 1981 and 1982. See Jaeger and ICRISAT (1981) for details of the survey methodology.

[2] Although simple man–land ratios suggest that the Sahel has ample land for expansion, extremely low land productivity combined with considerable livestock pressure means that the effective arable land base is quite limited.

Table 1. Characteristics of the Survey Zones and Samples

	Sahelian Zone	Sudanian Zone: Land Scarce	Sudanian Zone: Land Abundant	North Guinean Zone
Rainfall, millimeters per year	300–500	500–700	500–700	700–1,000
Length of season, days	90–120	120–140	120–140	140–170
Rainfall variability	high	moderate	moderate	low
Soils	poor	moderate	poor	moderate
Population density, persons per square km.	25	15	50	55
Power source	oxen	donkey, oxen	donkey, oxen	oxen
Mechanized operations	plowing	plowing, weeding	weeding, line tracing	plowing
Years since adoption	2–3	7–9	7–9	4–5
Average hours of use	85	240	140	60

Binswanger cite five conditions that are closely associated with demand for plowing services: (*a*) high farming intensity induced either by demographic growth or market access, (*b*) crops with high yield response to improved soil preparation, (*c*) an important proportion of heavy soils which respond well to plowing but which are difficult to work manually, (*d*) a long growing season (or at least a long preparatory rainfall period) to reduce the labor conflict between plowing and timely planting,[3] and (*e*) market conditions which assure an elastic demand for increased production. Although Pingali, Bigot, and Binswanger did not examine similar factors that affect the adoption of traction weeding, access to land for farm expansion is the major environmental determinant (Sargent et al.).

Average Product and Use of Animal Draft Equipment

The differences across the four study zones provide only partial support for the hypothesized regional variation in draft power potential cited above. The characteristics of the zones and samples, including the level of utilization of animal traction, are shown in table 1. In table 2, simple cross-sectional comparisons of various measures of average productivity are made for each zone between equipped households and nonadopters. While not conclusive evidence, such comparisons of average factor use and productivity patterns highlight relationships that are explored in depth below.

Although average use rates for animals and equipment were empirically associated with differences in average factor productivity, neither corresponded closely to initial cross-zonal expectations based on agroclimatic considerations. For example, average use rates were highest in the land-scarce Sudanian village (240 hours per season) followed by the land-abundant Sudanian village (140 hours). As expected, equipped Sahelian farmers used their animals at low levels (85 hours). But the lowest use was observed among north Guinean farmers (60 hours) who had adopted only plowing and ridging equipment but not weeders.

When resource use and average products are compared between adopters and nonadopters, significant differences are observed. Returns to land and labor among adopters were largest in the land-abundant Sudanian village, where both plowing and weeding had been mechanized (table 2). In the land-scarce Sudanian village where plowing was not done, revenue and area per worker were also markedly greater among adopters compared to nonadopters, while returns to land was less.[4] In the north Guinean villages, differences in average factor productivity were similar to those in the land-abundant Sudanian village, though smaller and not significant for returns to land. The labor–land ratio is significantly lower among households equipped with animal traction in both Sahelian zones and in the north Guinean zone (1981), supporting the hypothesis that traction is a labor-saving technology which, under land surplus conditions, permits area expansion. But across zones only weak and inconsistent yield differences are observed when comparing adopters with nonadopters. Higher yields for several crops occur only in the land-abundant Sudanian village and in the north Guinean zone, where draft power is used primarily for plowing.

The absence of significant differences in average returns to either land or labor in the Sahel, and only modest differences in the north Guinean zone, undoubtedly reflect the low utilization of animals and equipment in these zones. The central question, then, is how to explain the causes of low utilization. In the most arid Sahelian zone, the short growing season (hence brief period for effective use) and low yields are sufficent factors for explaining the limited opportunities to use draft animals productively. Where the rainy season is longer, such as in the north Guinean zone, possible explanations include the provision of inappropriate or incomplete animal-drawn implement sets, farmer inexperience with traction techniques, small work force at the household level, or limited access to land.

An additional constraint on utilization is the lack of well-developed rental markets for draft animals in tillage operations. This is primarily because of the synchronous nature of these tasks whereby demand for rental services during limited periods coincides with owners' own use. As

[3] Farmers in the West African semi-arid tropics generally prefer to plant their predominantly full-season, photoperiod-sensitive varieties directly with the early rains with no soil preparation in order to maximize their growing period. Under these conditions, mechanized plowing actually increases labor requirements by introducing an additional operation early during the season.

[4] Yields in the land-scarce Sudanian village were generally lower among traction farmers who had mechanized only the weeding operation in an effort to expand cultivated areas. Because of the relatively high pressure on the land, expansion occurred primarily onto marginal soils and/or at the expense of a reduced fallow period. Moreover, labor input per hectare over the expanded area cultivated was significantly reduced by traction households, contributing further to lower yields but increasing output per unit of labor.

a result, investments and recurrent costs of maintaining draft animals year-round must be offset during the short period when they are put into productive own-farm use.

Labor Savings—Substitution of Capital for Labor

Comparing farming systems where traction plowing replaces manual soil preparation, the labor-saving benefits of mechanization are unchallenged. However, whether animal traction equipment saves labor in weeding operations remains a controversial issue. Delgado and McIntire exclude a traction weeding activity from their model on the basis of the low propensity of farmers to adopt animal-drawn weeders observed in the past in many parts of the region. Citing evidence from Senegal, they argued further that traction plowing alone actually increases the labor required for weed control. However, based on a detailed review of all available farm surveys conducted in the francophone parts of the region, Sargent et al. reported labor savings in traction weeding of up to 60%. They attributed the low adoption of weeders observed in some West African locations to the still infrequent practice of line planting and to the difficulties experienced by early adopters in guiding untrained animals through standing crops. In support of the latter argument, Barrett et al. showed that the propensity to use traction weeding equipment in the eastern region of Burkina Faso increases directly with years of traction experience. Moreover, the ubiquitous employment of traction weeding systems in other semi-arid zones of the world where traction has a longer history, most notably in India, further supports the labor-saving hypothesis.

In order to test for labor-saving effects in the survey data, gross farm revenue was regressed on physical units of labor and nonlabor inputs and estimated rates of technical substitution of manual for animal traction labor. Characteristics of agricultural production in areas such as Burkina Faso present special problems for production function analysis. Thin rural labor markets prevent using wage rates for reliable labor cost comparisons by season and type. Capital inputs are insignificant except for animal traction and fertilizer, which are handled separately. And land abundant agricultural systems with no land market pose problems for valuing widely varying qualities of land. Aside from clearing costs and travel time to and from fields, the costs of bush land are negligible. While some variation occurs across crops, labor and land are used at fairly constant proportions; and, as a costless input, land can be excluded from the functional form (it is assumed to be used at the level that maximizes the returns to the costly factors of production). Only in the north Guinean region, where improving soil fertility can have substantial gains due to the importance of cotton, is substitutability between land and labor, or capital, an interesting issue.

As a result of the extremely low levels of purchased inputs as well as limited data on opportunity costs for household labor, gross rather than net farm revenue has been used in the econometric analyses. The investment costs and profitability of animal traction are considered later.

We used the following linear separable form:

$$\begin{aligned} \textit{TOTAL FARM CROP REVENUE (FCFA)} = {} & b_0 + b_1\, \textit{LABOR HOURS} \text{ (excludes harvest)} \\ & + b_2\, \textit{DRAFT TEAM HOURS} \\ & + b_3\, \textit{FERTILIZER} \text{ (kilograms)} \\ & + b_4\, \textit{MANURE} \text{ (kilograms)} + \epsilon. \end{aligned}$$

The implicit assumption is that human and animal traction labor are substitutable at a constant rate, and that returns to scale are constant. A standard Cobb-Douglas production function was estimated for all villages, and the hypothesis of constant returns to scale was retained. Most variation between households is caused by differences in family size and cultivated area, both of which covary closely.

Results in table 3 indicate large potential labor savings, with marginal rates of technical substitution (defined as the ratios of the estimated coefficients) between draft animal power and human labor significantly greater than one in all zones. The ratios are quite high where both coefficients are significant—10.4 in the Sahel, and 9.8 and 5.3 in the land-abundant and land-scarce Sudanian villages, respectively. The particularly high coefficients in the north Guinean zone probably reflect the exclusion of explanatory variables from the estimation, in particular the residual effects of past investments in soil fertility or differences in crop mix and soil type.

[a] To correct for heteroscedasticity, weighted least squares was applied dividing each observation by the number of residents in the household. T-values are in parentheses; significance levels are: * = .10, ** = .05, *** = .01.
[b] Marginal rate of technical substitution between animal draft team labor and manual labor.

Nevertheless, the coefficients are consistent with the expected high potential of traction tillage in that zone. Overall, these estimates provide persuasive evidence that, with two persons guiding a single donkey or even three persons required to guide a team of oxen, human labor is substantially more physically productive with traction equipment than when cultivating by hand.

The Learning Curve

High rates of technical substitution suggest adequate incentives for much greater equipment utilization than was observed in the survey. Previous studies, however, have suggested that a slow learning process in mastering animal traction techniques may lead to inefficient and low use immediately after adoption (Barrett et al., Lassiter, Sargent et al.). This in turn makes adoption of animal traction less attractive to farmers because of delayed benefits and the long payback period on their investment.

The learning curve is empirically estimated from the survey data using the following model:

$$TOTAL\ HOURS\ OF\ USE = b_0 + b_1\ YEARS\ SINCE\ ADOPTION + b_2\ (YEARS\ SINCE\ ADOPTION)^2 + \epsilon.$$

The length of time since initial adoption explains between 20% and 60% of variation in hours of use. The regression results (table 4) showed that the response curve estimated for the northern Guinea zone leveled off sooner than did those for the Sudanian zones. This reflects an "upper bound" on utilization for the plow and ridger in the north Guinean zone that was more limiting than the potentially higher utilization for farm-

Table 4. Estimated Relationship between Years of Experience and Hours of use of Animal Traction

Dependent Variable: Total Hours of Use

	Sudanian Zone		Northern Guinean Zone	
	Land Scarce (n = 60)	Land Abundant (n = 59)	1981 (n = 25)	1982 (n = 58)
Intercept	41.3[a]	24.9	7.1	−46.1
	(59)	(42)	(12)	(38)
Years since adoption	40.4***	19.7**	17.4**	40.1***
	(14)	(9)	(6)	(12)

	(.7)	(.4)	(.5)	(.8)
R-squared	0.3	0.2	0.6	0.3
F-value	7.4	6.4	6.0	5.1

Note: Nearly all traction farmers in our Sahelian sample had used draft power for the same number of years (three in 1981 and four in 1982), making estimation of this relationship impossible.
[a] Standard errors are in parentheses; significance levels are: * = .10, ** = .05, *** = .01.

ers who employ weeders, or weeders and plows, as among farmers in the Sudanian villages.

Direct estimation of the relationship between total farm product and experience would be extremely difficult because of high variability in the large number of factors affecting a household's production in a particular year. Area cultivated, however, is a more stable and direct indicator of the hypothesized effect of experience. In the two Sudanian zones where animal-drawn weeding was practiced among traction households, a quadratic regression equation was estimated between years since adoption, family size and composition, and area cultivated:

$$\begin{aligned} AREA\ CULTIVATED = b_0 &+ b_1\ WORKING\ MEN + B_2\ WORKING\ WOMEN \\ &+ b_3\ WORKING\ CHILDREN + b_4\ YEARS\ OF\ EXPERIENCE \\ &+ b_5\ (YEARS\ OF\ EXPERIENCE)^2 \\ &+ b_6\ ADDITIONAL\ DRAFT\ TEAMS\ OWNED + \epsilon. \end{aligned}$$

The results confirm a strong and statistically significant relationship (table 5, fig. 1), suggesting that after five or six years of experience, farmers can achieve area increases of two or more hectares.[5] The relationship between experience and farm size mirrors the pattern found between experience and utilization. Stated simply, these results indicate that new adopters do not benefit from animal traction primarily because they do not use it.

Table 5. Estimated Relationship between Experience with Animal Traction and Area Cultivated

Dependent Variable = Farm Size (hectares)	Sudanian Zones

[b] Several households possessed more than one donkey, pair of oxen, or a combination of the two.

A Linear Programming Model of the Farm

If animal traction is labor augmenting and some farmers are able to achieve high utilization and large benefits, why are adoption rates so low? The high initial cost and long learning period may prohibit some farmers from adopting because of poorly functioning credit markets, but our analysis suggests that other factors are involved. A linear programming model of the family farm was constructed to examine the effects of farm size (number of workers), restricted access to land, different equipment components, and low utilization of draft animals on the profitability of animal traction. Because the analysis compared manual, donkey, and oxen systems, technical coefficients were derived from the land-abundant Sudanian village, the only site where the number of observations permits specification of all three tillage systems. Up to fifteen production techniques were included for each major crop. These techniques were distinguished by differences in timing and level of labor inputs for planting, weeding, and plowing, each with its associated yield effects. All technical coefficients were derived from survey data.

The model employed a profit-maximizing objective function, augmented by a target MOTAD configuration that requires household subsistence needs to be satisfied with a specific

[5] This time-series inference from cross-sectional data must be qualified. If early adopters tend to be better farmers, then the inference may be incorrect. But this formulation controls for the possibility that use and area cultivated might be greater among more experienced households simply because early adopters may have larger family work forces. With family size and composition variables included, the regression results reject the hypothesis that the observed phenomenon simply results from large households having been the early adopters.

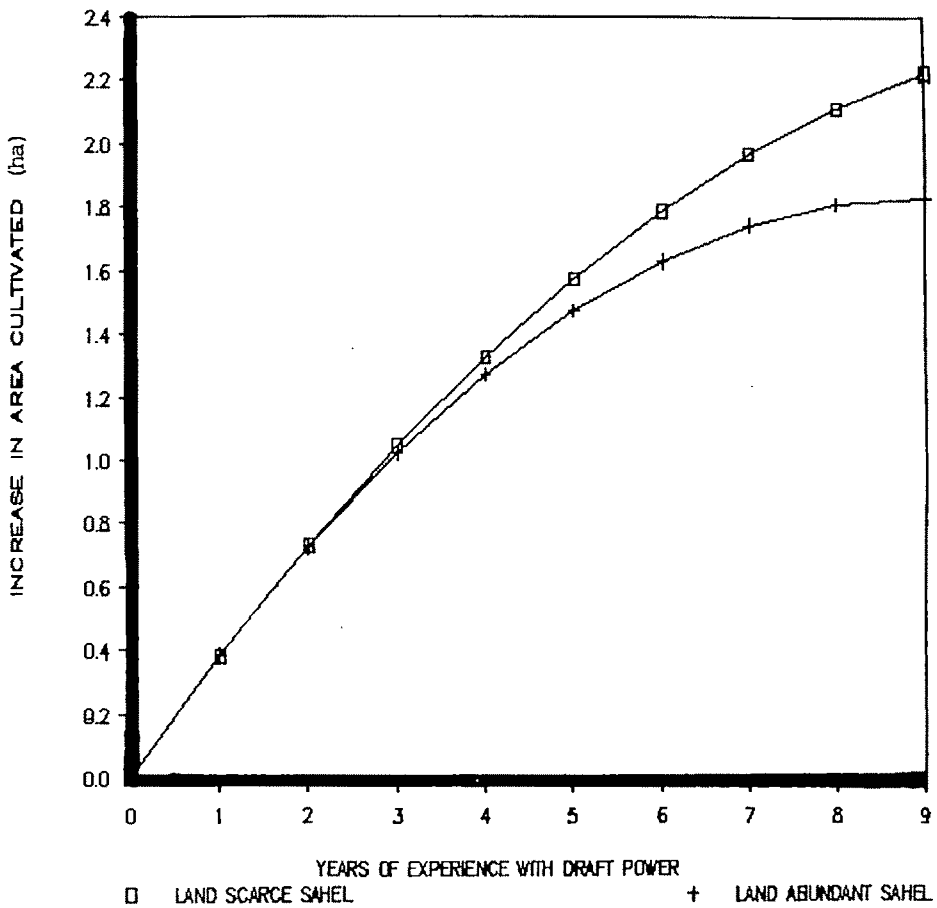

Figure 1. Estimated learning curve: regression results

degree of certainty.[6] Labor was limited to the family labor pool because of the absence of a significant, reliable rural labor market. The model allowed forty, thirty, and twenty-five hours per week for men, women, and children, respectively, and included consideration of household members' obligations for other domestic tasks as well as travel time to and from fields. The model also permitted substitution of labor types by age and sex, and with draft animals, at task-specific rates of substitution which reflect differences in performance derived from the survey data using regression estimates not presented here (Jaeger).

Three types of land were specified to reflect actual data on land availability, cropping patterns, and productivity in the survey village. Early planting and plowing were restricted in accordance with the likelihood of having sufficient moisture in the soil to perform those tasks. These latter parameters were derived from twenty-five years of secondary rainfall data combined with an analysis of the relationship between rainfall amounts and the number of succeeding days during which these tasks can be performed, based on the survey data.

Animal traction was introduced in the model

[6] Most farmers in semi-arid West Africa allocate resources first to assure their own subsistance requirements before maximizing income from marketed production. This behavior is incorporated into the farm model with a targeted MOTAD formulation (Hazell, Tauer) in which subsistance consumption requirements (defined in terms of cereal per adult male equivalent) are assured at an 80% probability with the constraints:

$$\sum_{i=1}^{n} C_{hi}X_i - S + Y_h \geqq 0 \; for \; h = 1, \ldots, 20, \text{ and}$$

$$\sum_{h=1}^{20} Y_h \leqq \lambda * S$$

where C_{hi} is a matrix of yields associated with the i cereal production activities for h states of nature, Y is vector of negative deviations from the target subsistance level s, λ is the total expected negative deviations from the target level over the h states of nature, and n is the number of crop production activities (Jaeger).

as an integer variable, making it available for use while imposing the year-round cash and labor costs of animal tending. Draft animal use, however, was determined endogenously, with the model employing animal traction at efficient levels consistent with the available household labor necessary for care and field work. By including animal traction as an integer variable, the modeled household was forced to own, rather than rent, the specific package of animals and implements, consistent with the near absence of rental markets.

Results

The basic solution of the farm model was consistent with observed farmer behavior (table 6). The ox plow used alone generated no acreage expansion, and draft team use was limited to only 60 hours. Very small yield increases resulted from ox plowing; but the cropping pattern shifted slightly to maize and bambara nuts, which are more responsive to deep soil preparation. Plowing did not enter the solution for other crop activities where the yield response is marginal, especially since the model realistically forced plowing to delay planting and to exacerbate the weeding labor bottleneck. By contrast, using weeding implements alone resulted in the cultivation of an additional four hectares, most sown with peanuts. Draft animal use increased to 300 hours.

When the model permitted use of the plow together with the weeder, net income doubled compared to the manual tillage solution and equipment use was maximized at over 400 hours. Traction plowing resulted in yield increases and

expanded acreage for the most responsive crops. Normally, plowing would have resulted in delayed planting and increased labor requirements during the peak weeding period when late planting continued. However, weeding implements overcame this bottleneck because the farmer could not only preserve the positive yield effects but also increase cultivated area. The predicted cropping pattern and levels and shifts in family labor use were quite close to those actually observed. These results support the hypothesis that the scarcity of weeding equipment in the north Guinean zone was a key element in explaining the surprisingly low use and factor productivity observed in that zone.

Sensitivity Analyses

By parametrically varying key constraints in the model, we also traced the effects of changes in utilization, size of farm work force, and land scarcity on cropping patterns and farm income. Hours of usage were restricted to various levels in order to simulate the effect of underutilization and the results were plotted as a curve relating utilization to increases in farm income (fig. 2). The model predicted that draft animal use could increase beyond the average levels observed, but not beyond the range observed in the survey data. The results further underscored the crucial importance of attaining high levels of use to be profitable.

Similarly, varying the number of family workers indicated that farm revenues were positively associated with family size (fig. 3). Smaller farms were disadvantaged because the labor required to maintain the draft animals is a larger share of total farm labor, and the small area that can be planted limits utilization of the draft animals for weeding and plowing to lower levels.[7]

[7] The mean number of active household members for rural families in Burkina is about seven and for all survey villages mean active family size for the manual tillage group was approximately half that of households using draft systems. Indeed, a common characteristic of nearly all animal traction studies in West Africa is that the mean family size among the animal traction households is nearly twice that of hand tillage units.

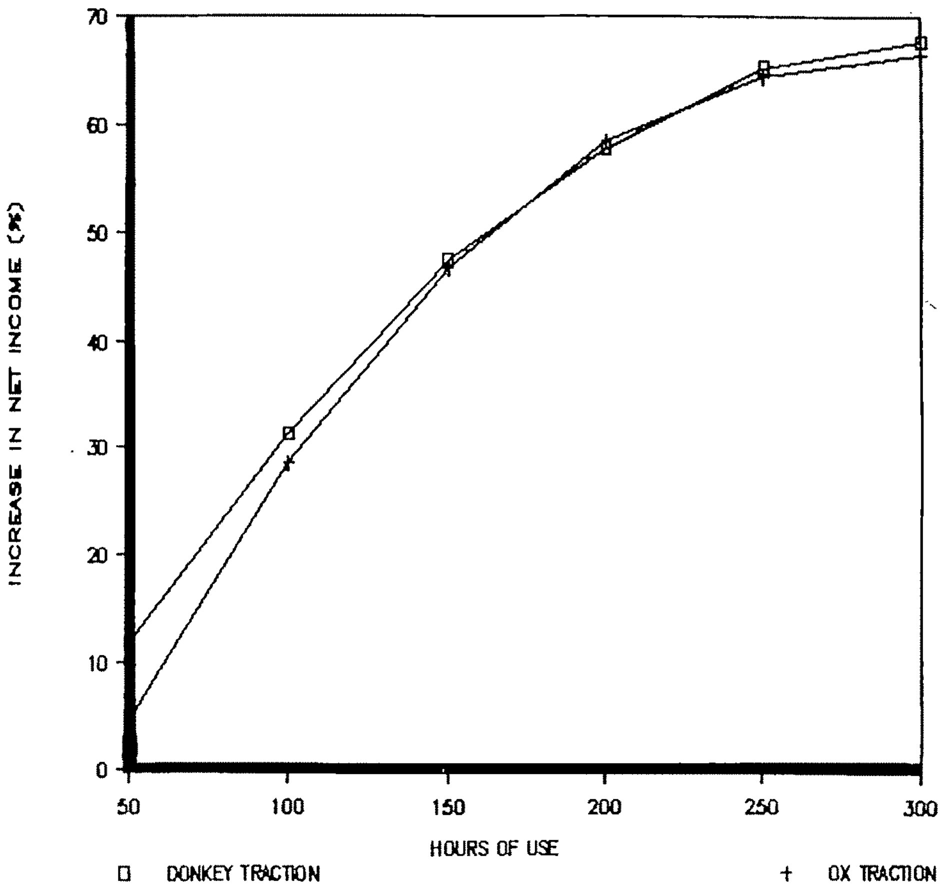

Figure 2. Farm income and traction utilization: LP model results

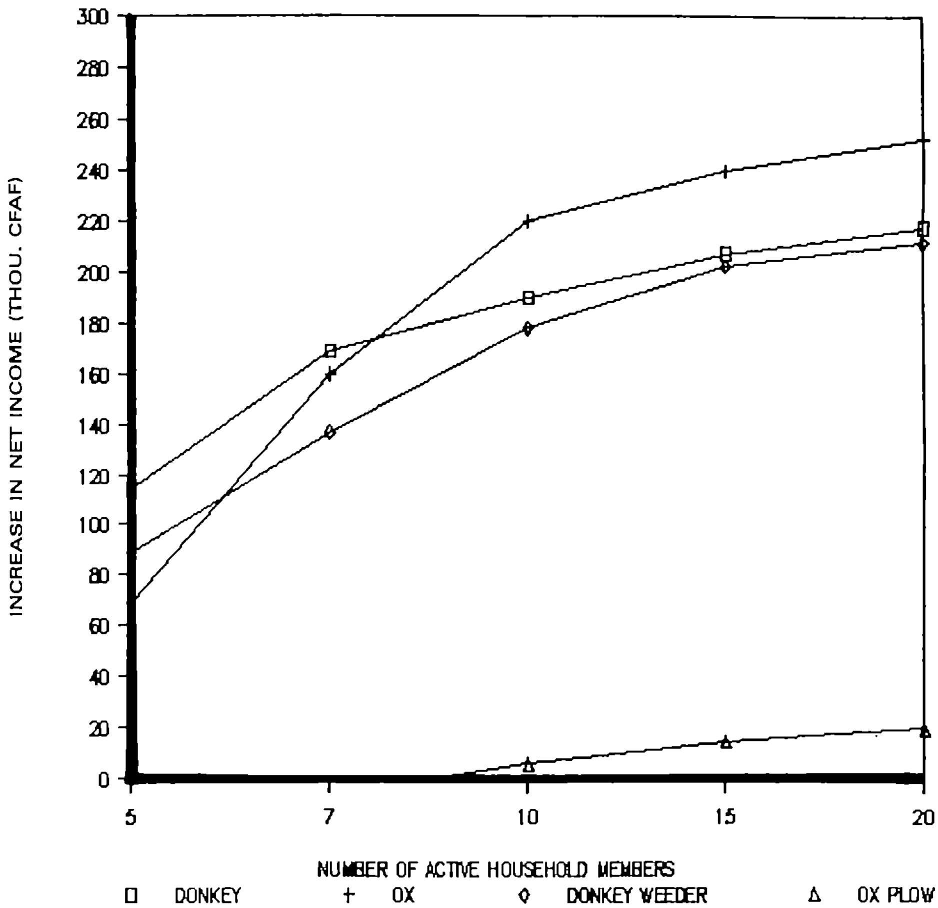

Figure 3. Economies of farm size and animal traction

Not all farmers in these regions have access to additional land or to land of sufficient quality to profit from extensification with animal traction. When area expansion was restricted in the model, the benefits of animal traction were substantially reduced. Although a small increase in yields with animal traction plowing permitted a marginal increase in gross farm income above that for manual tillage, the results underline the crucial importance of access to land to ensure profitability in these farming systems.

Return on Farmers' Investment

In a series of model runs, internal rates of return from eight-year partial budget streams were computed under several sets of assumptions about the rate of increase in utilization and final use levels. Costs of equipment, maintenance, depreciation, and expected losses due to risk of draft animal mortality were based on survey data.

The model predicted that the initial investment in the full equipment set is not recouped until the fifth year (using a 10% discount rate) when full benefits are also achieved. When partial budget streams were computed using benefits observed in the surveys, the resulting internal rates of return were 26% for ox traction and 35% for donkey traction; these differentials reflect the lower investment costs and comparable benefit streams for donkey versus oxen traction. Using the income gains predicted by the model but restricting utilization and learning to be consistent with observations, rates of return of 25% and 41% were estimated for oxen and donkey traction, respectively. When the learning period was cut by half, or when levels of utilization were increased by 50%, rates of return exceeded 40% for oxen traction and 60% for donkey traction.

Although these returns compare favorably with commercial banking rates, in regions where rural capital markets impose high risk premiums, interest rates can easily exceed these levels. Rates of return of between 35% and 70% likely are

inadequate for near-subsistence farmers for whom assets serve as the major means of covering production risks and meeting family emergencies. Households that have accumulated assets beyond that required to serve as crop insurance will perceive lower opportunity costs of capital and thus may be more willing to invest in animal traction.

The relative importance of these factors differs by region. In the Sahel, where production risks are higher, crop insurance substitutes are more important than, for example, in the north Guinean zone where higher and more assured rainfall and yields make intertemporal variation in production smaller and less critical. In short, the effect is to increase the implicit cost of capital in zones of higher risk which further constrains investment in traction systems.

Previous Work Reconsidered: The Harvest "Constraint"

The analysis presented here is consistent with most prior literature and field surveys, which generally found evidence of area expansion effects with the introduction of animal traction but only limited support for yield effects (Barrett et al., Sargent et al., Delgado and McIntire, Lassiter). Cases where evidence of achieved benefits was limited were usually associated with inexperienced farmers. In the Barrett et al. and Lassiter studies, for example, over half of the farmers in the sample had less than three years of experience and a similar share used their draft animals less than fifty hours during the year. Previous studies also gave insufficient weight to the distinction between plowing and weeding implements in determining the kinds of expected benefits.

However, the important work by Delgado, and later by Delgado and McIntire, differs from the main body of work on this subject in several respects, some of which were mentioned above. But their conclusions derive primarily from the assumptions made about the yield effects and the associated harvest labor requirements resulting from adoption of animal traction. Delgado's model relies upon research station trials to assume large increases in yield (120% for millet and sorghum, 190% for groundnuts, 230% for cotton). Harvest labor requirements are increased proportionally, and these labor requirements are concentrated in a single two-week period.

As a result of these assumptions, labor during this two-week period is severely constrained (becoming the only binding labor constraint) and is the pivotal determinant of his results in which oxen traction was unprofitable.[8]

This severe harvest labor constraint built into the Delgado model forces total area cultivated in the animal traction solution to be reduced by two-thirds and leaves more than half of available household labor idle throughout the entire cropping season. This result implies that, because of the anticipated crop losses from pest damage caused by delayed crop removal, farmers would stop planting when they judge that the expected harvest would exceed their ability to harvest it promptly. Such perceptions and behavior were not observed in any of the four systems examined in the present study, and no evidence of reductions in farm size resulting from the adoption of animal traction is found in other farm-level studies conducted in the region.

Concluding Comments

This study demonstrates that particular components of draft animal tillage systems can be profitably adopted by farmers in the West African semi-arid tropics when factors internal and external to the household production unit permit high utilization of animals and equipment. The conclusions follow from three central findings: first, animal draft power is significantly labor saving when used in appropriate tillage operations; second, high use of animals and equipment is crucial to achieving competitive returns on investment in them; and third, the capacity of farmers to use animal traction at high rates is a function of agroclimatic factors, equipment types, farmers' experience with the technology, and farm size.

The results confirm that animal-drawn weeding equipment can significantly raise labor productivity during the most critical labor bottleneck period. Across zones, the minimum marginal rate of technical substitution between manual and traction labor was greater than five. This result indicates high use potential for weeding equipment in those zones where land availabilities permit area expansion and where labor in other operations is not limiting. The use of both plowing and weeding implements offers considerable potential complementarity in re-

[8] Our survey data indicate that harvest lasts 3 to 8 weeks on major fields.

gions where land is available and the length of the growing season is sufficient.

The potential gains from animal draft power also vary by region depending on a broad set of agroclimatic and economic factors. The short rainfall season and light soils of the Sahel zone strictly limit potential utilization and profitability. The potential in the northern Guinean zone is greater because of a longer growing season, deeper soils, and the presence of an important cash crop, cotton.

Satisfying these exogenous regional conditions for a given equipment package, however, does not assure high utilization for individual production units. Animal traction systems are lumpy and display important economies of scale. Thin and inefficient factor markets mean that characteristics of individual production units are very important in determining which households can adopt traction systems profitably. Because equipment rental opportunities are tightly constrained by the synchronous nature of tillage operations, investment costs must be spread over a large operated area in order to achieve profitable use levels. A large household labor force is also advantageous for spreading the animal-tending costs over more individuals and for conducting nonmechanized farm operations on an expanded area. Initial capital requirements and returns to animals and equipment which are only marginally competitive with the opportunity cost of capital also tend to bias adoption to households with more abundant capital. And in regions where low and erratic rainfall makes agriculture riskier, the opportunity cost of a household's accumulated assets may be even higher because of their important role as a form of insurance.

Animal traction requires not only a large capital investment for farming households but also a major reallocation of family labor and the development of new skills. Both processes can delay achieving full utilization and benefits by up to seven years after initial adoption. During this period adopters can face a severe cash flow problem which, if exacerbated by unfavorable weather and poor harvests, can force asset-poor households into financial loss and divestment.

The implications of these results for mechanization policy are clear. Given the wide diversity which characterizes West Africa, equipment packages should be designed and targeted only to areas where agroclimatic conditions and available land permit high and profitable utilization. Further targeting of extension assistance within those areas to larger and better endowed farmers could improve adoption success. Such targeting would favor already privileged producers; that is, households located in higher potential zones and those more favorably endowed with land and other farm-level resources. But to promote adoption among farmers in marginal areas (to advance equity) and among those who lack the complementary resources needed to fully utilize the equipment and animals would only result in burdening them with untenable investments.

Finally, policy makers should recognize that continued population growth into the next century will eventually preclude sizable productivity gains solely from the labor saving, area expansion benefits of animal draft which currently predominate. As land becomes more scarce, technical change toward more intensive and sustainable yield-augmenting technologies will become increasingly crucial. Growth in the size and income of the nonfarm sector is likely to raise agricultural prices, further improving the economics of more intensive technologies. Where agroclimatic conditions permit high utilization, mechanized plowing will derive greater importance as deep tillage becomes an essential farm operation for those intensive systems.

Integration of Spatial Markets

Merle D. Faminow and Bruce L. Benson

Studies of spatial market integration draw their implications from a theory which assumes that there are no intraregional transport costs. An alternative theory is offered, based on the assumptions that buyers and sellers are spatially dispersed and intraregional transport costs are significant. This implies that the market is a linked oligopoly (or oligopsony) and that market integration tests are tests of alternative oligopoly price formation processes. For example, collusive basing-point pricing produces results typically assumed to imply efficiently integrated markets, while competitive FOB pricing does not. The theoretical implications are illustrated with an analysis of hog prices in Canada.

Key words: Canadian hog prices, spatial market integration, spatial oligopoly.

Spatial price relationships for agricultural and food commodities have been widely used to indicate market performance. For example, two generally accepted principles thought to underlie regional price differences are (Tomek and Robinson, p. 151): (*a*) price differences between any two regions (or markets) that trade with each other will just equal transfer costs; (*b*) price differences between any two regions (or markets) that do not engage in trade with each other will be less than or equal to transfer costs.

The seminal book by Takayama and Judge provides the necessary theoretical justification for these principles, given certain explicit assumptions. Of particular interest here is the assumption that all transactions within a region occur at a point; that is, no intraregional transportation costs apply (effectively, all buyers and sellers are located at a single point). Although some applied studies of spatial market integration directly acknowledge the importance of the Takayama and Judge formulation (e.g., Ravallion), others do not (Harriss, Jones).

A direct application of the two principles listed above is to test statistically whether price differences between regions (markets) are greater than, less than, or equal to transfer costs. Prices can also be compared to those which might exist under a "perfect" economic system. In practice, this has been done by solving a Takayama-Judge spatial equilibrium model for theoretical prices or price differences between regions (Leath and Blakley).[1]

A less direct application of the Takayama-Judge model, employing price responses between various regions or markets, has also been developed. If two sites trade with each other, price changes in one should lead to identical price responses in the other. Thus, Monke and Petzel (p. 482) define integrated markets as "markets in which prices of differentiated products do not behave independently." In the case of spatial markets, identical products are assumed to be differentiated by location, and statistical tests of interdependence between prices at different locations are employed to indicate the degree of market integration. Bivariate correlations of price series between pairs of markets that approach a value of 1.0 infer market integration (Jones, Stigler and Sherwin, Neal). Taken together, available studies using price correlation comparisons suggest that market integration is often quite low, although the markets appear to operate competitively. Problems with this statistical test have led researchers to advocate the

[1] Although it is widely known that a spatial equilibrium model can be solved to compute equilibrium price or price differences between regions, this is not often done. One problem is that actual transfer costs are determined in a market with supply and demand conditions, but a supply/demand component for transfer services is generally not included as one part of an empirical spatial equilibrium model (Seaver, p. 1370). In addition, the findings of Wallace suggest that actual and predicted price levels and differences are not closely correlated when a linear programming model is used to determine "predicted" prices.

use of statistical procedures that include lagged responses and/or consideration of normal seasonal fluctuations (Blyn, Harriss, Ravallion, Delgado).

In this paper we suggest a revised structural view of intermarket price interdependence by realistically assuming that buyers and sellers are both spatially dispersed and intraregional transportation costs exist—an obvious characteristic of agricultural and food markets. This approach alters theoretical expectations of price relationships in spatial markets and, therefore, alters the interpretation of market integration tests proposed by Ravallion. The next section examines relevant aspects of spatial price theory. This is followed by a section which delineates the Ravallion tests and suggests possible modifications in their interpretation. An application is then made to hog prices in Canada.

Price Relationships in a Spatial Market

A large literature deals with spatial competition in agricultural and food markets. The least-cost approach, based upon the location theory of Weber and Isard, examines the trade-offs between the costs of assembling inputs and distributing outputs. The relative costs of nontransferable inputs across potential sites, the cost of transporting transferable inputs to possible locations, and the cost of shipping finished products from these sites to markets are of primary concern. Spatial equilibrium models, based on linear or quadratic programming, have this theoretic base (e.g., Takayama and Judge, chap. 3).

Central to the solution of these models, and therefore predictions regarding price equilibrium conditions, is the assumption that a geographic area can be partitioned into a discrete number of regions in which all intraregional transfer costs are zero. Intraregional competition and trade can be characterized by the perfect competition model, and regional boundaries are assumed fixed.

A second spatial approach emphasizes locational interdependence, based upon the early writings of Hotelling and Smithies (e.g., Greenhut 1971). In markets where sellers and buyers are spatially distributed, transfer costs affect the net price received or paid. In food markets, consumers generally consider only those retailers who are located nearby even though many more retail outlets may exist in the economic market (Benson and Faminow). Similarly, in agricultural product markets, even when large numbers of buyers are located across a geographic area, farmers typically compare the prices in several proximate locations because of intraregional transport costs. That is, farmers differentiate between buyers on the basis of location. This suggests a second characteristic of spatial competition. Even when many sellers (buyers) are located in a geographic area, each considers only nearest rivals as major competitors, so linked oligopolistic (oligopsonistic) competition characterizes food retail (agricultural product) markets where expected pricing responses of rivals—conjectural variations—also determine pricing policy. Thus, spatial markets where both buyers and sellers are dispersed and transport costs are significant should not be characterized as perfectly competitive (Greenhut 1971). Furthermore, regional boundaries become a function of relative prices and do not remain fixed as prices change.

Market integration, that is, the process by which price interdependence occurs, can be directly deduced by developing a model of spatial oligopolistic (or oligopsonistic) competition. This model allows illustration of price reaction functions which form the theoretical basis for price interdependence (i.e., integration) in spatial markets.

In keeping with the spatial literature, the model given below is couched in terms of a few firms selling to spatially dispersed consumers located on a linear market (oligopoly). The theoretical example developed here will assume three spatially separated sellers, X, Y, and Z in figure 1, with consumers evenly distributed between X and Z. However, the results generalize to much larger numbers of sellers located at either the same sites (X, Y, and Z) or at numerous other sites, to unevenly distributed buyers and/or sellers, and to a two-dimensional space, although with increased mathematical complexity (magnitudes change but not comparative statics). In addition, they easily generalize to a market with relatively few buyers (e.g., at X, Y, and Z) and large numbers of spatially distributed sellers—oligopsony rather than oligopoly. This is an important point because some stages of the vertically linked series of markets which transform agricultural products into consumer goods (e.g., producer to processor markets) involve a few relatively widely dispersed buyers and much more numerous and more ubiquitously located sellers. Other stages, such as food retailing, readily lend themselves to spatial oligopoly modeling, however (Benson and Faminow). Therefore, the theoretical pre-

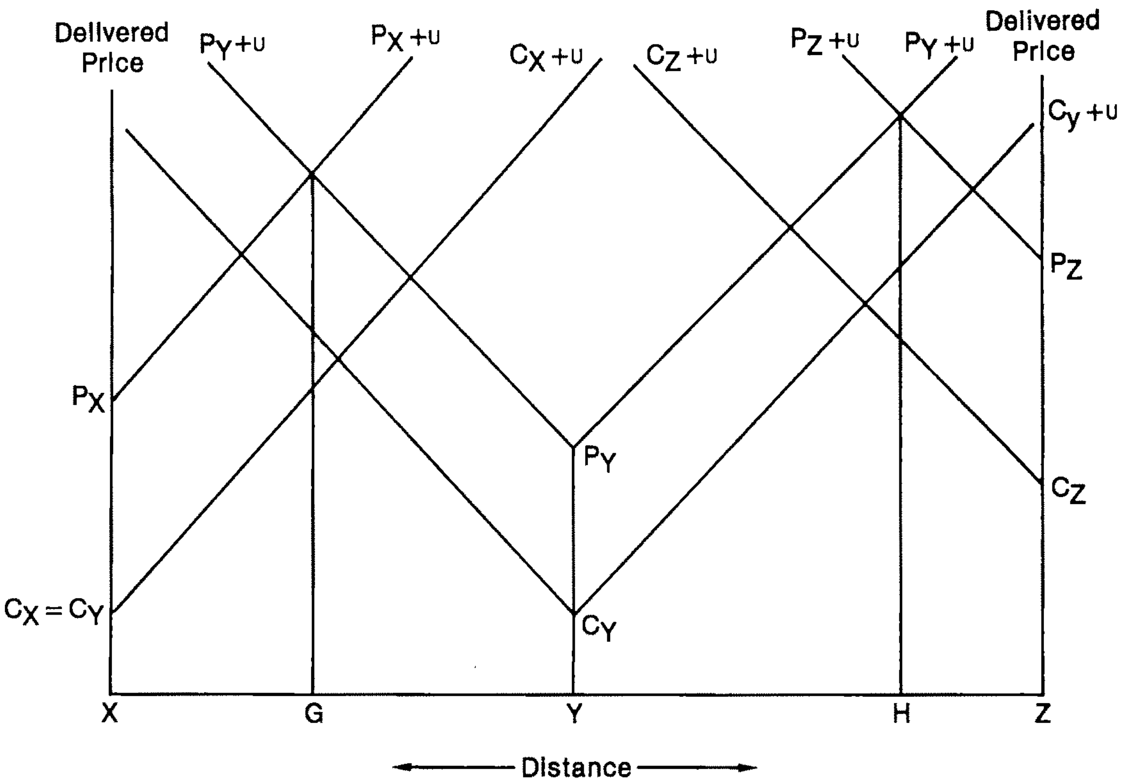

Figure 1. FOB pricing

sentation focuses on oligopoly in order to emphasize the generality of the market interdependence implications of spatial competition and to establish clearly these implications in the context of an extensive existing literature.

Spatial Competition under FOB Pricing

Assume identical consumers are evenly and continuously distributed between X and Z in figure 1. Let demand at each buying point for the physically homogenous product be of the form

(1) $$\bar{P} = a - (b/v)\, q^{v},$$

where $\bar{P}$ represents delivered price, q denotes quantity demanded, a and b are positive constants, and v is a constant parameter which can be positive or negative but greater than -1.[2] Delivered price, $\bar{P}$, consists of the price actually set by a firm, p, and transport costs. Assume for simplicity that a constant transport rate equal to unity exists for hauling the good one unit of distance. Thus, the delivered price from a selling site to any buying point is

(2) $$\bar{P} = p + u,$$

where u represents the units of distance to that point from the relevant seller's location. Combining (1) and (2) are solving for q yields

(3) $$q = \left[\frac{v}{b}(a - p - u)\right]^{1/v}.$$

Assume that each of the firms faces production costs consisting of a fixed cost component, F, and a variable cost which involves a constant marginal cost, c:

(4) $$C_i = F_i + c_i Q_i \; i = x, y, z.$$

The x, y, and z subscripts denote the three firms, while Q represents a firm's output. In a spatial world these fixed and marginal cost values need not be identical for survival of geographically separated firms. In fact, they are assumed to differ here in order to explore potential relationships between the three firms' prices. In particular, assume $c = c_x = c_y$, but $c_z > c$. Thus, z is a relatively high-cost producer. The schedules

[2] This functional form has been used extensively in the spatial literature, e.g., Greenhut and Greenhut, Benson (1980, 1984), Benson and Hartigan. Note that v must be greater than -1 in the FOB model which follows because we assume a constant marginal cost, and $v < -1$ implies an upsloping marginal revenue.

$c_i + u$ in figure 1 represent the relative marginal delivered cost relationships envisioned here.

In order to determine the profit-maximizing FOB mill price, the individual demands from equation (3) within each firm's service area must be aggregated:

$$(5)\quad Q_x = \int_0^G \left[\frac{v}{b}(a - p_x - u)\right]^{1/v} du = \frac{b}{v+1}\left[\frac{v}{b}(a - p_x)^{(v+1)/v} - \left(\frac{v}{b}(a - p_x - D)\right)^{(v+1)/v}\right],$$

$$(6)\quad Q_y = \int_0^{D-G} \left[\frac{v}{b}(a - p_y - u)\right]^{1/v} du + \int_0^{D-H} \left[\frac{v}{b}(a - p_y - u)\right]^{1/v} du$$

$$= \frac{b}{v+1}\left[2\left(\frac{v}{b}(a - p_y)\right)^{(v+1)/v} - \left(\frac{v}{b}(a - p_y - D + G)\right)^{(v+1)/v} - \left(\frac{v}{b}(a - p_y - D + H)\right)^{(v+1)/v}\right],$$

$$(7)\quad Q_z = \int_0^H \left[\frac{v}{b}(a - p_z - u)\right]^{1/v} du = \frac{b}{v+1}\left[\left(\frac{v}{b}(a - p_z)\right)^{(v+1)/v} - \left(\frac{v}{b}(a - p_z - H)\right)^{(v+1)/v}\right].$$

The Q_i represent the aggregate demand functions relevant to the FOB pricing firms, while G and H are distances over which X and Z, respectively, sell.

Profit for each firm is

$$(8)\quad \pi_i = (p_i - c_i)\,Q_i - F_i,$$

so profits are maximized when $d\pi_i/dp_i = 0$. Thus, for example, firm X's profit-maximizing decision is represented by

$$(9)\quad \frac{d\pi_x}{dp_x} = \left[\frac{v}{b}(a - p_x)\right]^{(v+1)/v} - \left[\frac{v}{b}(a - p_x - G)\right]^{(v+1)/v} + \frac{v+1}{b}(p_x - c_x)\left[\frac{v}{b}(a - p_x - G)\right)^{1/v}\left(1 + \frac{dG}{dp_x}\right) - \frac{v}{b}(a - p_x)\Big)^{1/v}\Bigg] = 0.$$

The oligopolistic nature of this pricing decision is represented by the boundary conjecture (dG/dp_x). The boundary between two FOB pricing firms' sales areas occurs where delivered prices are equal, so G arises where

$$(10)\quad p_x + G = p_y + (D - G), \text{ or}$$

$$(11)\quad G = \frac{1}{2}(p_y - p_x + D).$$

The boundary conjecture dG/dp_x clearly depends on X's expectations regarding Y's price response because

$$(12)\quad \frac{dG}{dp_x} = \frac{1}{2}\left(\frac{dp_y}{dp_x} - 1\right).$$

The precise value of p_x obtained from equation (9) depends on demand and cost parameters as well as on the size of firm X's sales area (G) and the boundary conjecture. Thus, x's reaction function might be characterized as

$$(13)\quad p_x = p_x\left(a, b, v, c_x, G, \frac{dG}{dp_x}\right).$$

Of course, G, given in equation (11), is a function of p_x and p_y; so, through G, the price set by the firm at X depends on the price set by the firm at Y. Furthermore,

$$(14)\quad H = \frac{1}{2}(p_y - p_z + D),$$

$$(15)\quad p_z = p_z\left(a, b, v, c_z, H, \frac{dH}{dp_z}\right), \text{ and}$$

$$(16)\quad p_y = p_y\left(a, b, v, c_y, G, H, \frac{dG}{dp_y}, \frac{dH}{dp_y}\right).$$

Assumption of specific parameter values and conjectures allows simultaneous solution of equations (11), (13), (14), (15), and (16) for equilibrium prices, such as p_x, p_y, and p_z in figure 1. Thus, the price set by X is, through G, p_y and H, a function of the price set at Z. In

fact, given $v < 0$, (if $v > 0$, price discrimination rather than FOB pricing is likely, as explained below) comparative statics analysis implies that

$$\frac{dp_x}{dp_z} > 0. \tag{17}$$

The actual comparative statics analysis of the integration process implied by this model is not presented here because the results are intuitively obvious (Benson 1980). If firm Z lowers price for some reason, H would expand ($D - H$ would shrink) prompting firm Y to lower price; G in turn would shrink ($D - G$ would expand), and firm X would lower its price. The price set by X is impacted by cost and demand conditions which Z faces (and vice versa). By the definition of geographic market integration used here, X, Y, and Z are all in the same market because each firm's price depends on the prices set by the other two.

However, this integration likely represents a dynamic process if spatial oligopolistic competition underlies the price formation process. Initial price reactions and their feedbacks can lead to additional price changes as the market adjusts toward a new equilibrium for comparative statics analysis. Reaction functions such as equations (13), (15), and (16) imply a sequence of reactions and re-reactions. The full price adjustments can take time. In addition, as already noted, the fully adjusted equilibrium prices need not be equal or differ exactly by transport costs (recall the discussion of fig. 1). Indeed, given $c_z > c_x$, $p_z > p_x$, but $p_x + u_{xz} > p_z$ (u_{xz} represents the distance from X to Z). Prices may be highly interdependent in a spatial setting without net price uniformity (price less transportation costs) rising. Arbitrage only guarantees that prices at different spatial buying sites will not differ by more than the transport cost of shipping the product from one site to another. It does not imply that prices net of transfer costs will be the same; indeed, they can differ for many reasons in a spatially interdependent market.

The magnitude of price responses need not be identical. Consider firm Y's response to firm X's original price change. Firm Y may wish to regain its lost geographic market share by exactly matching X's price change, but such a response will also generate a price reaction by Z (as well as further price changes by X). If Y does not fully match X's price change, then Y serves as a buffer between X and Z. The larger the number of intermediate selling sites between two specific sellers, the weaker the price linkage. Mulligan and Fik (1988, 1989) demonstrate mathematically that a distance-decay effect occurs in spatial competition models. More distantly located competitors are linked indirectly and, *ceteris paribus*, the price response will be weaker.

Spatial Price Discrimination

The value of the parameter v in the demand function [equation (3)] is one important determinant of whether or not firms in the market can practice price discrimination. A spatial firm which faces no direct competition for customers at a particular buying point will set a profit-maximizing price at that point unless prevented from doing so (e.g., by consumer arbitrage or by legal/institutional constraints). For instance, firm X will set price for a customer located at X by equating marginal revenue and marginal cost:

$$\bar{P}_x (1 - (1/e)) = c_x, \tag{18}$$

where e is the own-price elasticity of demand. From equation (1), $d\bar{P}/dq = -bq^{v-1}$ and $bq^v = v\,(a - \bar{P})$, so

$$e = \bar{P}/(v(a - \bar{P})). \tag{19}$$

Substituting (19) into (18) provides

$$\bar{P}_x (1 + v) - va = c_x. \tag{20}$$

For consumers located at some distance from X, transport costs are netted from marginal revenue or added to marginal cost

$$\bar{P}_{xd} (1 + v) - va = c_x + u, \tag{21}$$

where $\bar{P}_{xd}$ represents delivered price from x to any point in the market. Solving equation (21) for $\bar{P}_{xd}$ yields firm X's discriminatory delivered price schedule.

$$\bar{P}_{xd} = (1/(1 + v))\,(va + c_x) + (1/(1 + v))u. \tag{22}$$

The first term on the right-hand side of equation (22) is the price at point X [see equation (20)], while the slope of the delivered price schedule as u increases is $(1/(1 + v))$. The slope of an FOB schedule is unity because the transport rate is assumed equal to one. Therefore, a delivered price schedule with a slope of less than one implies freight absorption and discrimination in favor of distant buyers (or against near buyers). A slope greater than one, implies phantom freight and discrimination in favor of near buyers (against

distant buyers). Thus, $v > 0$ means that freight absorption is profitable, while $v < 0$ implies that it is not.

Profitable consumer resale or arbitrage is not possible when freight is absorbed. However, arbitrage should prevent phantom freight and discrimination in favor of near buyers (see Benson 1984 for more detail). Thus, $v < 0$ implies that the best spatial firms can likely do is set FOB prices. As a consequence, the theoretical analysis of price discrimination was developed assuming $v > 0$ and FOB pricing assuming $v < 0$. Of course, FOB pricing may also arise when price discrimination is prevented even though $v > 0$ (e.g., legal sanctions may prevent spatial price discrimination, or consumers may pay the transport cost themselves by traveling to pick up the product).

Similar schedules to equation (22) can be derived for Y and Z. Assuming the same parameters, discriminatory schedules would produce higher price intercepts and flatter schedules than the FOB schedules depicted in figure 1. Consumers would buy from the firm offering the lowest delivered price, so market boundaries occur where delivered price schedules are equal.

Because prices are set independently at each buyer site, interdependence only applies where delivered prices are equal. In the example developed here, this condition occurs at only one point between X and Y and between Y and Z. Spatial price discrimination is not restricted to monopoly, and spatial competitors can discriminate in order to invade rival's markets, producing considerable market overlap (Greenhut and Greenhut). Thus, discrimination may break the linkage that implies extensive market integration, as under FOB pricing. A complete breakdown in market integration requires constant marginal costs.

When marginal costs are upsloping, the spatial price discriminator does not equate marginal cost to the net marginal revenue on sales at each buyer location. Instead, the relevant marginal cost is that which applies to the last unit of total sales over the firm's entire marketing area (Greenhut, Norman and Hung, pp. 180–96). Spatial markets consisting of price discriminatory oligopolists are interdependent because price changes in one firm affect its market fringe, moving neighboring firms down along their original marginal cost schedules. Thus, other firms lower profit-maximizing discriminatory prices to all buyer locations, firms consider rival responses to potential price adjustments, and lagged price adjustments and feedbacks characterize the adjustment to an equilibrium. Thus, market integration implications similar to those discussed above under oligopolistically competitive FOB pricing can arise under oligopolistically competitive spatial price discrimination, given nonconstant marginal costs.[3]

Basing-Point Pricing

Basing-point pricing systems generally result from an organized oligopoly arrangement, either price leadership or collusion (Greenhut, Scherer). Under this system the mill or base price is set at a particular production site (sites under a multiple base-point system) or basing point, and the delivered price to any buyer location is the base price plus transportation costs.

In figure 2, site A is the basing point. The price at A (p_A) is set, perhaps jointly by several spatially dispersed firms or perhaps by the basing point firm (or firms) acting as a price leader. Firms located at other sites (for example, B and C) adopt the delivered price schedule from A ($p_A + tu$) for all sales. Thus, prices net of transport costs are equal. Sales to the left of B and C's locations require freight absorption by the firms at those locations, while sales to the right involve "phantom freight" because they would normally charge a price below P_B and compete for market area such as in figure 1. If the price at A were to change for some reason, all other prices would change by the same amount. Furthermore, collusion or price leadership implies virtually instantaneous price adjustments with no feedbacks.

Clearly, prices are interdependent as the intuitive definition of market integration suggests. Moreover, any arbitrarily chosen regional boundaries established over this market (e.g., at political boundaries) would result in interregional trade because the prices charged by all firms are exactly the same at all locations. Consumers do not differentiate among sellers by location. Thus, the firm at A probably sells through the AC space and firms at B and C may sell all the way back to A if freight absorption is not too great. Under an effective single basing-point system, prices will differ exactly by transportation costs.

[3] The constant marginal cost assumption also influences comparative statics under FOB pricing, given $v > 0$ (thus assuming some legal or institutional constraint prevents price discrimination). If $v > 0$ and marginal costs are constant, a seller may raise price as its market shrinks (Benson 1980, Benson and Hartigan, Capozza and Van Order); so equation (17) need not hold. However, an upsloping marginal cost will reestablish (17) even when $v > 0$.

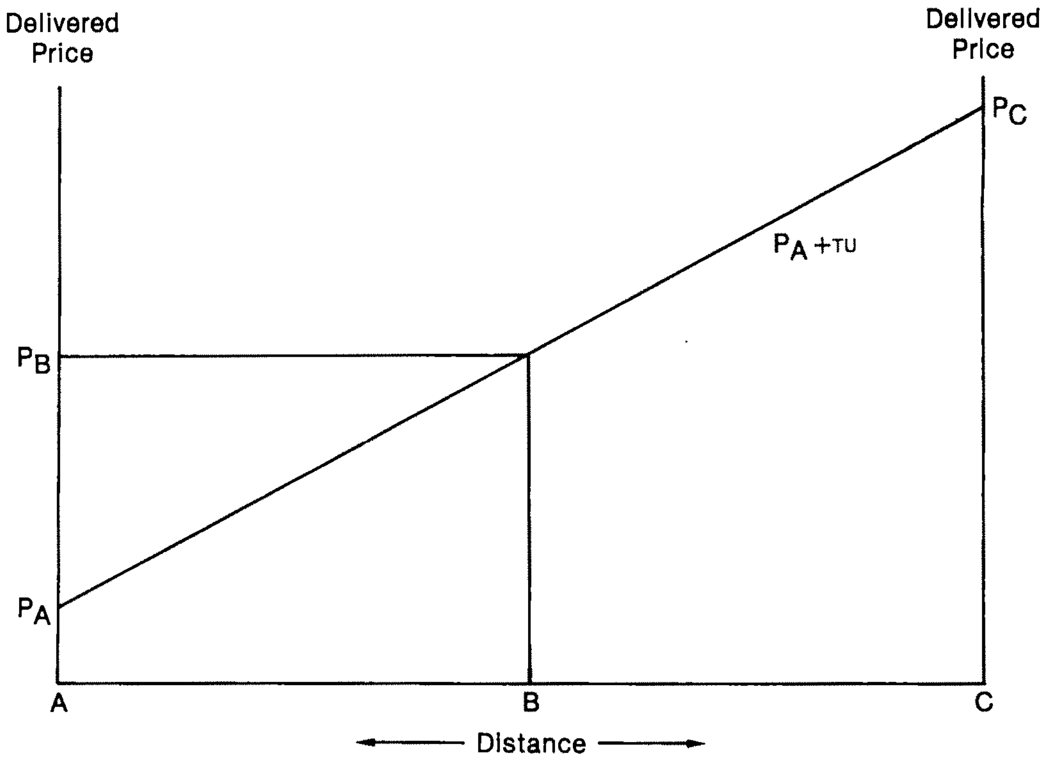

Figure 2. Basing-point pricing

Implications for Empirical Tests

Market integration studies have emphasized applications to food staples in developing countries, most notably Nigeria and India (see Harriss for a review of these studies). Different, but related, empirical techniques have been used to test spatial market integration. High price correlations are often taken to infer integration (e.g., Jones, Harriss, Uri and Rifkin, Blyn). In addition, price differences between markets, relative to transfer costs (Stout and Feltner, Hays and McCoy) or normal seasonal fluctuations (Delgado), provide other approaches to determining integration. However, these empirical tests of market integration are essentially tests to see which spatial pricing system underlies the price formation process.

The usual definition in the literature is that integrated markets are those where prices are determined interdependently. This has generally been assumed to mean that price changes in one market will be fully passed on to other markets (or the result has been derived from a Takayama-Judge model). In this context, Ravallion (p. 105) discusses both short- and long-run market integration. With short-run integration, price changes are fully and immediately passed on to other markets with no lagged effects. Long-run integration requires that a unit price change is fully passed on over time, but with the potential for lagged effects. In principle, however, the Ravallion approach is consistent in its general expectations with the price correlation and net spatial price difference approaches described earlier, which rely on all activity within a region taking place at a point.

Ravallion developed his market integration tests for a central urban market with interlinked local (rural) markets where trade with the central market was the dominant feature of the price formation process.[4] This implies that the rural

[4] Systems like this have been characterized as "competitive" basing point systems (e.g., Haddock). In fact, base point pricing can conceivably arise without collusion or price leadership, but the necessary conditions are very limiting (Benson, Greenhut, and Norman). Thus, a more accurate characterization of such a system is that competitive FOB pricing exists between various central marketing points, and the rural markets are simply transshipment terminals. Alternatively, they may actually involve a price leadership basing point arrangement with the central market firms as the dominant firm price leaders and the smaller rural firms as price takers. The following presentation suggests a statistical procedure for determining whether such a system is competitively or cooperatively produced.

markets are relatively minor. However, extension to a linked framework, as developed above, is straightforward by evaluating all bivariate price relationships in the spatial area under consideration. Consider the model

$$(23)\quad X_t = \sum_{j=1}^{n} a_j X_{t-j} + \sum_{k=0}^{m} b_k Z_{t-k} + E_t,$$

where X_t and Z_t are the prices in location X and Z at time t, E_t is the error process, and the fixed parameters are a_j and b_k. In this simplified version of the Ravallion model the market integration tests remain as

(*a*) independence:

$$b_k = 0\ (k = 0, 1, \ldots, m),$$

(*b*) short-run integration (strong form):

$$b_0 = 1;\ a_j = b_k = 0 \quad (j = 1, 2, \ldots, n;\ k = 1, 2, \ldots, m),$$

(*c*) short-run integration (weak form):

$$b_0 = 1;\ \sum_{j=1}^{n} a_j + \sum_{k=1}^{m} b_k = 0,$$

(*d*) long-run integration:

$$\sum_{j=1}^{n} a_j + \sum_{k=0}^{m} b_k = 1.$$

Price interrelationships in the system can be evaluated by considering all market pair combinations.

The test of independence requires that the contemporaneous and lagged price effects at one location are independent of prices at another location ($b_k = 0$, all k). If consumers and producers are spatially distributed, this possibility is predicted by spatial price discrimination with constant marginal costs. Under the other spatial pricing systems described above, $b_k \neq 0$ is expected to hold.

The strong form of short-run integration requires basing-point pricing if consumers and producers are not concentrated at single points and prices differ by transportation costs. In this case price adjustments are fully reflected in the same time period ($b_0 = 1$) with no lagged effects ($a_j = b_k = 0$; j, $k \neq 0$). An effective basing-point system is the only theoretical spatial model which produces this expectation, given spatially distributed buyers and sellers, and significant intraregional transport costs.

The other widely used spatial models (competitive FOB oligopoly and spatial price discrimination) do not produce these same expectations. Basing-point systems generally arise out of a noncompetitive institutional structure and are not usually considered desirable.[5] (They are frequently attacked under the antitrust laws.) This suggests that concerns about the lack of market integration in some empirical studies should be discounted; their expectations are not based on a model which is expected to generate desirable results if buyers and sellers are spatially dispersed in the market being examined. Under such circumstances, the evidence (previously interpreted as a lack of market integration) suggests that cartelization, in the form of a perfect basing-point pricing system, is not generally observed. Strikingly, the typical conclusion that highly integrated markets (that is, markets in which price movements are highly correlated and prices differ exactly by transport costs) are caused by competition and imply an efficient market is reversed: such markets are caused by collusive basing-point pricing and tend to be relatively inefficient.

The weak version of the short-run integration test requires that the lagged effects vanish on average ($\Sigma_{j=1}^{n} a_j + \Sigma_{k=1}^{m} b_k = 0$); this result is consistent with a less than perfect basing-point system. For instance, if this test applies for all the relevant marketing points, then a tacitly collusive arrangement may exist and time is required to search for the new equilibrium price. If, on the other hand, the result applies for a subset of the interdependent marketing points, then an incomplete cartel may be in operation. Price adjustments set in motion within the base point system cause competitive reactions by firms outside the basing-point arrangement which feed back into the base point price determination process, and vice versa. Thus, lags and feedbacks are evident between firms in the basing-point arrangement and those outside it.

The two short-run integration tests constitute tests of an underlying basing-point system. Along with the Takayama and Judge criterion of equal spatial prices (net of transfer costs) over time, these tests allow examination of the underlying market behavior in spatial price generation.

In the long-run integration test, all contemporaneous and lagged effects sum to one. In effect, price changes in one region net out, in a dynamic fashion, to exactly equal price changes in the other. Because each short-run test implies

[5] Such a system might be competitively produced, but the necessary conditions are quite limiting. See footnote 4 for related discussion.

long-run integration (Ravallion), this test is a feature of a basing-point system. However, the short-run tests may be rejected and the long-run test accepted. This would be consistent with price reactions equal to one for the competitive FOB oligopoly and perhaps for increasing marginal cost price discriminatory models. However, exact price matching over the longer term is not a requirement of these models, only an empirical possibility.

An Empirical Example: Hog Prices in Canada

Weekly hog prices for five Canadian cities (Edmonton, Calgary, Saskatoon, Winnipeg, and Toronto) were taken from the Livestock and Meat Trade Report for the period 9 January 1965 to 20 December 1975. Data for Montreal, the other major hog market in Canada, were not published subsequent to July 1970, so this city is excluded from the analysis. In total, 572 weekly observations of average prices were available. From 9 January 1965 to 28 December 1968, Grade A dressed hog prices were used, and for the remaining time Dressed Index 100 hog prices were analyzed. This eleven-year period includes the time period when electronic exchanges were introduced for marketing hogs; thus, it represents a potential readjustment in the price formulation process in Canada. Therefore, the ability of the empirical tests to detect changes in pricing systems could be evaluated. In addition, this general time period has had considerable scrutiny. Concerns about market pricing efficiency resulted in a major price study (Canadian Pork Council) and in a major anticombines case.[6]

Both buyers and sellers are spatially dispersed, and transportation costs are significant; so these data are particularly well suited for evaluation of spatial prices and the form of the pricing system which is implicit in the market integration tests. Generally, hog production is dispersed across Canada, although not always evenly, and slaughtering occurs at the major cities included in the analysis. Hog production in each province was relatively constant during the 1965–69 time period. However, during the 1970–75 period, production trended slightly upward in Saskatchewan and Manitoba, decreased somewhat in Ontario, and fluctuated around the historical average in Alberta (Canada Pork Council). A substantial exported surplus developed in Saskatchewan and Manitoba, and the price differential in these provinces fell relative to U.S. prices. In addition, during this time Ontario moved from a position of self-sufficiency to a pork deficit.

Other institutional changes were occurring during the early 1970s. In Alberta (1969), Saskatchewan (1973) and Manitoba (1971) marketing boards for hogs were formed, and the pricing system changed. Electronic exchanges for selling hogs were instituted in Alberta and Manitoba, while Saskatchewan developed a formula pricing system for sales from the marketing board to packers. Finally, substantial rationalization of the packing industry occurred. In response to low levels of capacity utilization (estimated at about 30% by Canada West Foundation) a large number of plants either closed or ceased to slaughter hogs.

The price data were first differenced in order to represent price changes from period to period. This allowed the data analysis in a manner consistent with the theoretical models. Price levels were highly volatile during the latter half of the data set, and the transformation to price differences allows the empirical evaluation to focus on the interdependence of price changes rather than price levels. This is consistent with the theoretical model development, and interactions of price changes between different locations should not be seriously affected by volatile overall price levels. Additionally, based upon inspection of the estimated autocorrelation functions, differencing transformed the data into stationary series.

The empirical tests are based on estimated OLS versions of equation (23) for all combinations of market pairs for the five cities (20 regressions per time period). This exhaustive evaluation of price response equations allows the evaluation of the form (or forms) of spatial pricing for hogs. A simultaneous approach would evaluate the generalized version of equation (23) using vector autoregression. However, beyond the well-known tendency of severe multicollinearity using this approach, there is an additional cost. Weaker price responses, caused by the linked interdependence of spatial oligopoly pricing systems, should be observed in the $\bar{R}^2$s resulting from the OLS estimates of equation (23) for each market pair. With more intermediary markets the price response is less direct. This information would be lost by using vector autoregression.

The data were divided into two time periods for analysis. The first coincides with the period

[6] *Reason for Judgment in Her Majesty the Queen* v. *Canada Packers Inc. and Intercontinental Packers Ltd.*

of relative stability in the market (9 Jan. 1965 to 25 July 1970), while the second represents a period with considerable institutional change (1 Aug. 1970 to 20 Dec. 1975). The criterion for determining the break point is arbitrary. However, it coincides with the date after which prices for Montreal ceased to be publicly reported by Agriculture Canada, and it allows evaluation of any differences in pricing systems during the two periods. Therefore, the sensitivity of the empirical procedure to structural and institutional factors can be evaluated.

The correct dynamic process given in equation (23) cannot be determined theoretically. Mechanical procedures can be applied (Bessler and Brandt) when a priori information is not available. In all cases, the Ljung-Box Q-statistic of the unrestricted regressions implied that autocorrelation was not a problem when eight lags were specified.[7] Therefore, the empirical tests are all conducted with eight lags (n, m = 8).

Evaluation of the market integration or spatial pricing tests involved F-tests of the regressions implied by equation (23) with the tests imposed as constraints, combined with analysis of spatial price differences. Tables 1 and 2 show the F-statistics for the two time periods and table 3 reports means and standard deviations of price differences between Toronto and the other markets.

Price differences. Price differences between Toronto and the other markets display different results for the two time periods. In period 1, price differences generally correspond to differences in transfer costs. For example, the average Toronto-Calgary difference is \$3.52, while the Toronto–Saskatoon difference is \$2.74. The Toronto–Edmonton price difference is roughly equivalent to transfer costs reported by the Canadian Pork Council. During the second period, the relationship between Toronto prices and the other markets changes considerably. Not only are price differences greater in all cases (probably reflective of general price inflation during the period), but they tend towards equality. Thus,

[7] Initial testing with four lags resulted in rejection of the null hypothesis of no autocorrelation. In addition, although choice of lag is by nature a difficult issue, eight weeks was a sufficient number to allow for interactive pricing between competing regions to run its course. "Hannan's Criterion" (Hannan) was suggested by a reviewer as an alternative ad hoc procedure. "Long-run" in these types of tests should be interpreted with caution because long-run in the normal economics sense is not being tested.

in period 2 relative prices across markets no longer reflect differences in transfer costs to other markets.

Independence. In all cases the null hypothesis of independence is rejected. Thus, no evidence of price discrimination is found under conditions of constant marginal costs in either period.

Perfect basing-point pricing. The strong version of short-run integration is rejected in all cases. Thus, there is no evidence of a perfectly functioning basing-point pricing system during either period. In several cases inspection of the individual regression coefficients indicated that $b_0 = 1$, but lagged effects were significant.

Table 3. Means and Standard Deviations for Price Differences

	TOR–CAL	*TOR–EDM*	*TOR–SAS*	*TOR–WIN*

Period 2				
Mean	4.42	4.20	4.40	3.51
S.D.	1.53	1.59	1.43	1.31

Incomplete basing-point pricing. In period 1, the weak form of the short-run integration test is not rejected in six cases. Prices in the three western markets appear to be interrelated by a loose form of basing-point pricing where Calgary is the basing point. The evidence suggests an unidirectional system where (*a*) Edmonton bases on Calgary; (*b*) Saskatoon bases on Edmonton and Calgary; (*c*) Winnipeg bases on Saskatoon, Edmonton, and Calgary. This western basing-point system is apparently competitively linked with Toronto, however, and this may explain the observed lags and feedbacks.

In period 2 the results are considerably different; in only one case do we fail to reject the weak-form constraint. In the second period, prices in Edmonton continue to be based on Calgary prices.

The evidence from this test is striking. The data indicate that the more widespread basing-

point system evident in period 1 broke down. This result contrasts with the anticombines case, cited earlier, which alleged price fixing by the Alberta-based packers throughout the entire eleven-year period.

Long-run price matching. In period 1, the restriction of exact, but lagged, price matching is rejected in ten cases. In Calgary and Edmonton, price changes in one market are fully reflected in the other, but neither fully reflects changes in the other three markets. The intermediate cities, Saskatoon and Winnipeg, fully reflect other markets, while this test is always rejected for Toronto.

The results are considerably different for period 2. In all cases this restriction is not rejected for Calgary and Edmonton, while it is only accepted for Saskatoon and Winnipeg when Toronto prices are used as independent variables. Once the basing-point pricing system broke down, the magnitude of price interactions and responses between markets changed substantially. In particular, lagged responses became more important for the two Alberta markets.

Distance decay effects. The unrestricted $\bar{R}^2$s for the two periods are given in tables 4 and 5. The distance-decay feature of spatial competition is evident in both periods. The $\bar{R}^2$-values decline with distance and/or the number of intermediate points, reflecting the linked nature of the price reaction functions given above. However, differences between the two time periods are evident. In particular, the increased pricing interdependence associated with the disappearance of the basing-point system is evident in the $\bar{R}^2$-values. The relative importance of Saskatoon and Winnipeg price changes as predictors of Calgary and Edmonton price changes is diminished. In general, $\bar{R}^2$-values are lower for all markets in period 2. Because of the increased competition associated with the breaking down of the basing-point system, the $\bar{R}^2$s of the paired market price responses are reduced. This is caused by a more rivalrous price determination process where price changes in additional markets must be considered. Thus, a lower level of correlation between any pair of price series should be expected.

Market efficiency. The marketing boards established in Alberta, Saskatchewan, and Manitoba were initially proposed to create more equitable and efficient markets for slaughter hogs. The electronic marketing systems implemented in Alberta and Manitoba were designed to create more competitive bidding by packers. In Saskatchewan, a formula pricing arrangement was developed to link provincial prices more closely to other markets. In all three cases, the primary emphasis was on designing pricing systems that facilitated exchange and reflected underlying

supply and demand conditions. None of the marketing boards was given authority to manipulate prices through supply management.

The disintegration of the basing-point system and movement to a more competitive FOB system roughly coincided with the introduction of these marketing innovations. However, other institutional changes (interregional supply/demand balances and rationalization of the packing industry in western Canada) were also occurring, so it is difficult to clearly establish a direct causal link. Adomowicz, Baah, and Hawkins suggest that shifts in market interdependency between Alberta and other major markets may have been caused by institutional changes instituted by the marketing board in Alberta. However, given the theoretical arguments presented above, the implications for market efficiency would be interpreted somewhat differently. High levels of price interdependence, in conjunction with price differences between hog buying locations that reflect transportation costs, is symptomatic of a collusive (overt or tacit) pricing system.

Conclusions

Studies of integration for spatial markets have explicitly or implicitly drawn their implications from a theory of market price formation which assumes no intraregional transport costs. Such studies have primarily relied upon price correlations and regressions that analyze the dynamic price adjustment patterns. Rarely, if ever, have prices been found to be highly correlated and differ between two points by transportation costs, thus indicating that the markets under study are not highly integrated and perhaps that they are not very efficient. An alternative theoretical interpretation for such results is suggested here, based on the assumptions that both buyers and sellers are spatially dispersed and intraregional transport costs are significant. These assumptions imply that the market is a linked oligopoly (or oligopsony). The implications of this alternative theory are illustrated by focusing on market integration tests proposed by Ravallion which allow certain predictions of various spatial pricing systems that may underly oligopoly (oligopsony) market price formation to be examined. For example, when combined with the criterion that prices between two points should differ by transportation costs, short-run integration standards are effectively tests of basing-point pricing.

To illustrate the implications of the theoretical analysis, the Ravallion methodology was applied to hog prices in Canada. Noncompetitive pricing, in the form of a basing-point pricing system for hogs, was detected for a subgroup of Canadian hog markets between 1965 and 1970. The tests were sensitive to institutional characteristics of the market. The results suggest that this pricing system disintegrated during the 1970–75 period, a time when substantial changes in the Canadian hog market occurred, and was replaced by a more competitive FOB pricing system.

The Value of Weather Information in Market Equilibrium

Bruce A. Babcock

Increased accuracy of weather forecasts does not necessarily increase commodity supply or farmer welfare. This study presents a stylized model of competitive production with rational expectations and demonstrates that improved weather information harms farmers facing an inelastic demand. Contrary to the conclusions of previous studies, the decline in farmer welfare does not require an expansion in expected supply. Better weather information may signal farmers to produce less on average under an inelastic demand. A supply decrease occurs when increases in the physical productivity of applied inputs are dominated by adverse price consequences.

Key words: market equilibrium, rational expectations, value of information, weather forecasts.

Widespread drought reinforces the notion that random weather processes can have both micro and macro effects on farmers. The productivity of farm inputs is affected as are output and input prices. Forecasts about weather, therefore, can affect the decisions of farmers in two ways: first, from the direct impact on physical productivity, and, second, through the profitability effects of expected price changes.

The impacts of weather forecasts on the physical productivity of input decisions are well studied (e.g., Byerlee and Anderson; Tice and Clouser; Rosegrant and Roumasset; Hashemi and Decker; Baquet, Halter, and Conklin; Stewart, Katz, and Murphy). However, the impacts of weather information on market prices have received little attention. One exception is Lave's analysis of the California raisin industry. He concludes that even a modest increase in supply from rainfall protection would lower total industry profits because of the inelastic demand for raisins. Thus, the raisin industry as a whole would be better off with less than perfect weather forecasts. However, Lave stopped short of examining how raisin producers would react to the knowledge that better weather forecasts lead to lower average prices. Presumably, the supply of raisins would decrease, thereby ameliorating some of the adverse price effects.

Typically, the value of information to an individual producer is calculated as the difference between expected returns (or utility) using the information and expected returns without the information, with both expectations taken with respect to the more informed distribution. The aggregate value of information is the sum of the individuals' values. Both the individual and the aggregate value of information are nonnegative using this approach. Lave's analysis reveals the problem with calculating the value of information when the use of the information can lead to price effects. Such market effects cannot be captured by the usual method of calculating the value of information.

Farmers' reactions to the knowledge that the use of information will change output price depend on whether they act cooperatively or noncooperatively. Monopoly models can be used to examine how farmers will use information if they cooperate in setting output levels. Such collusive behavior may characterize decisions by farmers who grow crops covered by marketing orders that effectively control quantities, and hence, prices. However, most crops are not covered by marketing boards, and individual producers generally make their own supply decisions. Widely available information that is used by many producers can create a price externality (external to the control of individual producers). Models of noncooperative behavior must be used to capture these effects.

The purpose of this paper is to examine how

Bruce A. Babcock is an assistant professor, Department of Economics and Business, North Carolina State University.

Paper No. 12424 of the Journal Series of the North Carolina Agricultural Research Service, Raleigh.

The author thanks Jim Chalfant, Paul Fackler, Bill Foster, and Kerry Smith for their insightful comments on earlier drafts.

the value of weather information is changed with improvements in the accuracy of forecasts when farmers act noncooperatively. Farmers are assumed risk-neutral, rational, and competitive. Further, each farmer is assumed to contribute a sufficiently small fraction of total output, so any individual's supply decision does not affect output price. Under these conditions better weather information could lead to a lower aggregate value of information. It is also shown, in contrast to Lave, that this result does not require an expansion in average supply.

The Model

Consider a competitive farmer with a crop yield which depends on the level of a controllable input, x, and an uncontrollable weather input, w, the level of which is known after x is applied. For simplicity, assume that w can only take on two values, w_g and w_b, and that the historical probability that w_g occurs is q. Denote the production function facing the farmer as

$$y = f(x, w),\ w = w_g \text{ or } w_b, \tag{1}$$

where y represents yield per acre. It is assumed that $f(x, w_g) > f(x, w_b)$ for all x.

To highlight the relationship between one region's weather forecast and output price, total supply is assumed to come from a single representative farmer. This farmer operates with the production function given by (1). In addition, this farmer is a risk-neutral price taker with rational expectations concerning output price. Although the demand function is nonstochastic, the price that the farmer will receive is stochastic before the weather variable is observed because of uncertain output. This formulation allows joint consideration of production and price uncertainty (Newbery and Stiglitz).

The assumption that the industry consists of one competitive producer with rational expectations is equivalent to assuming a large number of identical producers, none of which is large enough to affect output and each of which has rational expectations. The assumption of rational expectations means that each producer knows how the rest of the producers in the market will respond to changes in information, so the resulting distribution of output price is implied by the aggregate actions of all producers. No individual producer will find it profitable to diverge from what is optimal for all other producers because the action of any single producer does not affect output price.

Suppose that the farmer receives a probability forecast about the future level of w when x is applied. Let ρ represent the forecasted probability that future weather will be w_g. Assume that the forecaster is "correct" in that w_g occurs 60% of the time when the forecaster says that the probability of receiving w_g is 60%. Assume that farmers adopt the forecasted probability as their own posterior probability.[1] Let $g(\rho)$ denote the probability distribution function of ρ. The probability forecast ρ can take on any value between 0 and unity depending on observable weather conditions before the forecast is made and on the skill of the forecaster.

The farmer chooses the level of a variable input to apply after receiving a given forecast of future weather. The objective function and first-order condition for a specific value of ρ (e.g., $\rho = \rho_0$) are

$$\max_x E(\pi|\rho = \rho_0) = \rho_0 P[f(x, w_g)]f(x, w_g) + (1 - \rho_0)P[f(x, w_b)]f(x, w_b) - P_x x,$$

$$\rho_0 P[f(x, w_g)]f_x(x, w_g) + (1 - \rho_0)P[f(x, w_b)]f_x(x, w_b) - P_x = 0, \tag{2}$$

where $P(\cdot)$ is the demand function. Denote the solution to (2) as $x(\rho_0)$.

When choosing the level of x to apply, the farmer does not consider the change in output price implied by the level chosen because any single farmer faces a perfectly elastic demand curve. However, because the farmer uses all available information, the price distribution used to choose x in (2) is consistent with the choice of x. If this were not true, the farmer's choice would be suboptimal. Therefore, the derivative of output price with respect to input use does not appear in (2).

This concept of equilibrium naturally follows from the assumptions that no farmer is large enough to affect price and that farmers act noncooperatively. Relaxing either of these assumptions would yield another type of equilibrium (Cornes and Sandler).

[1] This paper does not focus on how farmers process information; rather, it focuses on the effects of more reliable forecasts on the value of information. The translation of objective probabilities (data) into posterior probabilities with Bayes' rule would needlessly complicate the analysis. To give the analysis a more Bayesian interpretation, ρ can be considered a posterior probability formed by processing a signal from the weather forecaster, rather than a forecast itself. The results developed in the paper are applicable to either interpretation.

The value of weather information is given by

$$(3)\quad VI = \sum_{\rho} \{\rho\pi[x(\rho), w_g] + (1-\rho)\pi[x(\rho), w_b] - \rho\pi(x_h, w_g) - (1-\rho)\pi(x_h, w_b)\}g(\rho),$$

where $\pi(\cdot)$ is the profit function for different forecasts, and x_h is the optimal amount of x employed using historical weather probabilities. Because x_h is not a function of ρ, the last two terms in (3) can be written

$$-\pi(x_h, w_g)\bar{\rho} - \pi(x_h, w_b)(1-\bar{\rho}),$$

where $\bar{\rho} = \Sigma\rho g(\rho)$ measures the weighted sum of conditional probabilities that good weather will occur. Given the assumption of correct forecasts, $\bar{\rho} = q$.

Increases in forecast accuracy come about with fewer forecasts of ρ in the vicinity of q, and more around zero and one. Perfect forecasts are given by forecasts of $\rho = 1$, $q \cdot 100\%$ of the time, and $\rho = 0$ the rest. This probability framework closely follows that developed in Winkler, Murphy, and Katz.

To calculate the value of improved information requires a recalculation of VI for a new probability distribution of ρ. The value of improved information is the difference between VI under the old distribution and VI under the new distribution. The difference measures the change in an industry's willingness to pay for weather information given that the industry currently is basing its decisions on historical weather probabilities. Because q is invariant to the probability distribution of ρ, it is sufficient to look at how expected profits of the information user change to gauge how the value of information changes as forecast accuracy increases (assuming that the forecasts remain correct).

The large number of possible values of ρ hampers a general qualitative exploration of the effects of increases in forecast accuracy. Restricting the number of possible forecasts increases the tractability of the problem. The remainder of the paper will focus on the effects of weather information assuming that there are only two possible values for ρ. With probability c, $\rho = \rho_g$, and with probability $1 - c$, $\rho = 1 - \rho_b$.[2] A further restriction is placed on the relationship between ρ_g and ρ_b by the assumption that $\Sigma\rho g(\rho) = q$. The restriction is that

$$(4)\quad \rho_b = \frac{1-c-q}{1-c} + \frac{c}{1-c}\rho_g.$$

Increases in forecast accuracy can be obtained by either increasing ρ_g or ρ_b. Assuming that c is held constant as forecast accuracy increases implies that for a given increase in ρ_g, a corresponding increase in ρ_b is defined by (4).

The value of weather information can now be written as

$$(5)\quad VI = c[\rho_g\pi(x_g, w_g) + (1-\rho_g)\pi(x_g, w_b)] + (1-c)[\rho_b\pi(x_b, w_b) + (1-\rho_b)\pi(x_b, w_g)] - q\pi(x_h, w_g) - (1-q)\pi(x_h, w_b),$$

where x_g and x_b are the optimal levels of x under the two values of ρ (ρ_g and $1 - \rho_b$).

Effects of an Increase in Forecast Accuracy

The value of information as defined in (5) is a function of forecast accuracy, which is represented by ρ_g. Because by (4), ρ_b is a function of ρ_g, changes in ρ_g affect both x_g and x_b. Differentiating the first-order condition (2) with respect to x and ρ (replacing ρ with its appropriate value) determines how input use changes as the forecasts become more accurate.

$$(6)\quad \frac{\partial x_g}{\partial \rho_g} = \frac{P[f(x_g, w_g)]f_x(x_g, w_g) - P[f(x_g, w_b)]f_x(x_g, w_b)}{-H_g},$$

$$(7)\quad \frac{\partial x_b}{\partial \rho_b} = \frac{P[f(x_b, w_b)]f_x(x_b, w_b) - P[f(x_b, w_g)]f_x(x_b, w_g)}{-H_b},$$

where H_g and H_b are the derivatives of (2) with respect to x_g and x_b. If demand is not upward sloping and if f is concave in x, both H_g and H_b are strictly negative.

How input demand changes as weather forecasts become more accurate depends on the relative magnitudes of output price and the mar-

[2] A forecast of $\rho = \rho_g$ can be considered a forecast of good weather. A forecast of $1 - \rho_b$ implies that the probability of w_b occurring equals ρ_b, so it can be considered a forecast of bad weather. Here good and bad weather refer only to output effects of weather.

ginal product of x under each of the weather states. By assumption, for a given level of x, $P[f(x, w_g)] < P[f(x, w_b)]$. Inputs x and w will be defined as production substitutes if $f_x(x, w_g) < f_x(x, w_b)$ and production complements if $f_x(x, w_g) > f_x(x, w_b)$.

Equation (6) can be unambiguously signed only when x and w are substitutes. When this occurs, both $P[f(x_g, w_g)] < P[f(x_g, w_b)]$ and $f_x(x_g, w_g) < f_x(x_g, w_b)$, so (6) is negative. When x and w are complements, the second inequality is reversed and (6) cannot be definitely signed. The condition for signing (7) is the same. When x and w are substitutes, $P[f(x_b, w_b)] > P[f(x_b, w_g)]$, $f_x(x_b, w_b) > f_x(x_b, w_g)$, and (7) is positive. Complementarity between x and w reverses the last inequality and the sign of (7) becomes indeterminant.

Signing (6) and (7) with complementarity between x and w depends on the responsiveness of output price to changes in supply and the degree to which the slope of the marginal product function of x is changed by weather. With a perfectly elastic demand curve, (6) is positive and (7) is negative. But if demand is quite inelastic, the negative price effects when good weather occurs are more likely to outweigh the positive productivity effects. The functional forms of the production and demand functions play a central role in determining how input use and supply change as weather forecasts become more accurate.

An exploration of necessary and sufficient conditions needed to sign the input, supply, and profit changes coming from improved weather information when w and x are complements proved quite fruitless. Instead, particular function forms are used to sign the effects. The forms used here assume that weather affects supply multiplicatively and that the demand function has constant elasticity. Let

$$(8) \qquad f(x, w) = g(x)T(w) \; w = w_g \text{ or } w_b,$$

where $g_x > 0$ and $T(w_g) > T(w_b)$, represent the case of production complements. To focus on the elasticity of demand let

$$(9) \qquad P[f(x, w)] = [f(x, w)]^{-\alpha},$$

where $\alpha > 0$. The (constant) elasticity of demand is $-\alpha^{-1}$. Using these functional forms, (6) and (7) become

$$(10) \qquad \frac{\partial x_g}{\partial \rho_g} = \frac{-g_x}{g_{xx} - \alpha g^{-1} g_x^2} \cdot \frac{T(w_g)^{1-\alpha} - T(w_b)^{1-\alpha}}{\rho_g T(w_g)^{1-\alpha} + (1 - \rho_g)T(w_b)^{1-\alpha}},$$

$$(11) \qquad \frac{\partial x_b}{\partial \rho_b} = \frac{-g_x}{g_{xx} - \alpha g^{-1} g_x^2} \cdot \frac{T(w_b)^{1-\alpha} - T(w_g)^{1-\alpha}}{\rho_b T(w_b)^{1-\alpha} + (1 - \rho_b)T(w_g)^{1-\alpha}}.$$

Given that $g_{xx} < 0$, the signs of (10) and (11) are determined by the value of α. When $\alpha < 1$ (i.e., demand is elastic)

$$T(w_g)^{1-\alpha} - T(w_b)^{1-\alpha} > 0,$$

which implies that

$$\frac{\partial x_g}{\partial \rho_g} > 0 \text{ and } \frac{\partial x_b}{\partial \rho_b} < 0.$$

The signs are reversed if demand is inelastic.

Rewriting (5) as

$$VI = cE_g(\pi) + (1 - c)E_b(\pi) - E_h(\pi),$$

where the subscript on the expectations operator denotes the weather distribution used to maximize expected profits, shows clearly how to determine the marginal value of weather information as the information becomes more accurate. As noted above, changes in forecast accuracy do not change the *ex ante* expected profits of the farmer who does not use the information. The marginal value of better weather information, therefore, can be written as

$$(12) \qquad \frac{\partial VI}{\partial \rho_g} = c\frac{\partial E_g(\pi)}{\partial \rho_g} + (1 - c)\frac{\partial E_b(\pi)}{\partial \rho_b}\frac{\partial \rho_b}{\partial \rho_g} = c\left\{\frac{\partial E_g(\pi)}{\partial \rho_g} + \frac{\partial E_b(\pi)}{\partial \rho_b}\right\}.$$

Applying the envelope theorem to the partial derivatives of the two profit functions results in

$$(13) \qquad \frac{\partial E_g(\pi)}{\partial \rho_g} = P[f(x_g, w_g)]f(x_g, w_g) - P[f(x_g, w_b)]f(x_g, w_b) + [\rho_g f(x_g, w_g)P'[f(x_g, w_g)]f_x(x_g, w_g) + (1 - \rho_g)f(x_g, w_b)P'[f(x_g, w_b)]f_x(x_g, w_b)]\frac{\partial x_g}{\partial \rho_g},$$

$$(14)\qquad \frac{\partial E_b(\pi)}{\partial \rho_b} = P[f(x_b, w_b)]f(x_b, w_b) - P[f(x_b, w_g)]f(x_b, w_g) + [\rho_b f(x_b, w_b)P'[f(x_b, w_b)]f_x(x_b, w_b) + (1 - \rho_b)f(x_b, w_g)P'[f(x_b, w_g)]f_x(x_b, w_g)]\frac{\partial x_b}{\partial \rho_b}.$$

Determining the signs of (13) and (14) is straightforward. The first terms in the two expressions measure the expected profit effects from a change in expected weather.[3] When demand is elastic (inelastic), revenue in the high output, low price state is greater (less) than the revenue in the low output, high price state. The second term measures the impacts on expected profits from the expected price change brought about by a different input use. Because demand is downward sloping, the sign of this effect is opposite the sign of the change in input use.

When demand is elastic and x and w are substitutes, (13) is positive and (14) is negative. The two effects work in the same direction for each equation. However, when demand is inelastic the signs cannot be determined unambiguously by simple inspection.

When x and w are complements and the two functional forms in (8) and (9) are appropriate, some algebraic manipulations and the substitution of (10) and (11) result in

$$(15)\qquad \frac{\partial E_g(\pi)}{\partial \rho_g} = \frac{g^{1-\alpha}g_{xx}}{g_{xx} - \alpha g^{-1}g_x^2}[T(w_g)^{1-\alpha} - T(w_b)^{1-\alpha}]$$

$$(16)\qquad \frac{\partial E_b(\pi)}{\partial \rho_b} = \frac{g^{1-\alpha}g_{xx}}{g_{xx} - \alpha g^{-1}g_x^2}[T(w_b)^{1-\alpha} - T(w_g)^{1-\alpha}].$$

When demand is elastic ($\alpha < 1$), $T(w_g)^{1-\alpha} > T(w_b)^{1-\alpha}$, so (15) is positive and (16) is negative. The signs are reversed when demand is inelastic.

To sign (12) requires additional knowledge about the relative magnitudes of x_g and x_b. This is true even with the more restrictive functional forms used to examine the changes when x and w are complements. To indicate what factors determine the sign of (12) when increases in w increase the marginal product of x, let $g(x)$ be a Cobb-Douglas function. That is, let

$$(17)\qquad f(x, w) = Ax^{\beta} \cdot T(w)\ w = w_g \text{ or } w_b,$$

with $T(w_g) > T(w_b)$. The remainder of the paper will utilize this particular functional form.

Changes in the Value of Information

Using (17), (12) becomes

$$(18)\qquad \frac{\partial VI}{\partial \rho_g} = \frac{c(1-\beta)}{1-\beta(1-\alpha)}[T(w_g)^{1-\alpha} - T(w_b)^{1-\alpha}][g(x_g)^{1-\alpha} - g(x_b)^{1-\alpha}].$$

The sign of (18) depends on the relative magnitudes of x_g and x_b and on the elasticity of demand. The solutions to the first-order conditions with the production function in (17) are

$$(19)\qquad x_g = K[\rho_g T(w_g)^{1-\alpha} + (1-\rho_g)T(w_b)^{1-\alpha}]^{1/1-\beta(1-\alpha)}, \text{ and}$$

$$(20)\qquad x_b = K[\rho_b T(w_b)^{1-\alpha} + (1-\rho_b)T(w_g)^{1-\alpha}]^{1/1-\beta(1-\alpha)},$$

where

$$K = \left[\frac{\beta A^{1-\alpha}}{P_x}\right]^{1/1-\beta(1-\alpha)}.$$

The size of x_g relative to x_b is determined by the relative magnitudes of the two bracketed terms in (19) and (20) because $1 - \beta(1-\alpha) > 0$. Noting that $\rho_g + \rho_b - 1 > 0$, which is the same as $\rho_g > q$ [see expression (4)], some straightforward algebra shows that the bracketed term in (19) is greater (less) than its (20) counterpart when demand is elastic (inelastic). Thus, $x_g > x_b$ when demand is elastic, and $x_g < x_b$ when demand is inelastic.

If demand is elastic, $g(x_g) > g(x_b)$, $g(x_g)^{1-\alpha} > g(x_b)^{1-\alpha}$, and $T(w_g)^{1-\alpha} > T(w_b)^{1-\alpha}$, which implies that the marginal value of information increases with an increase in forecast accuracy.

[3] At first glance, one would think that the sum of the first two terms in expressions (13) and (14) must equal zero since the long-run or historical frequency of weather has not changed. But what has changed are the conditional probabilities of supply and price under each weather state. For example, given that w_g occurs, it is more likely that x_g will have been applied with an increase in ρ_g. Thus, with an elastic demand, expected supply, given that w_g occurs, increases. Similarly, it is more likely that x_b will have been applied when w_b occurs, so expected supply given w_b drops. The net effect is positive because, with x and w being complements, more output will be forthcoming in weather state w_g than is lost in w_b.

But, when demand is inelastic, the marginal value is negative. In this case, $T(w_g)^{1-\alpha} < T(w_b)^{1-\alpha}$, but because $x_g < x_b$, $g(x_g)^{1-\alpha}$ remains greater than $g(x_b)^{1-\alpha}$.

The decline in the value of weather information as information becomes more accurate appears to be a counterintuitive result. That is, it appears to violate the principle of optimality in which an action would not be taken if an individual is made worse off by the action. The argument here is different. Each farmer acts optimally by fully utilizing the weather information. Ignoring the information when all other farmers are using it would make a farmer worse off. Therefore, the value of improved information to an individual farmer is positive. The total industry may be worse off with better information because of negative price effects. If the industry could collectively decide on a position about the possibility of improving the accuracy of weather information, the decision would be to not make the improvement.

The result that agricultural producers facing an inelastic demand can be made worse off from better information is similar to the finding that average farmers who are forced to ride the technological treadmill by adopting new technologies can be made worse off (Wilcox and Cochrane). But, whereas this argument relies on a supply expansion to lower profits, it can be shown that aggregate farmer profits can decrease even when average supply decreases.

Changes in Input Use

First, consider how the average use of x changes as the weather forecast becomes more accurate. Define average use of x as

$$\bar{x} = cx_g + (1 - c)x_b.$$

The change in average use of x due to an increase in ρ_g then is written,

$$(21)\qquad \frac{\partial \bar{x}}{\partial \rho_g} = c\left\{\frac{\partial x_g}{\partial \rho_g} + \frac{\partial x_b}{\partial \rho_b}\right\}.$$

With x_g and x_b given by (19) and (20), expression (21) becomes

$$(22)\qquad \frac{\partial \bar{x}}{\partial \rho_g} = \frac{cK}{1 - \beta(1 - \alpha)}[T(w_g)^{1-\alpha} - T(w_b)^{1-\alpha}][R_1^{\phi} - R_2^{\phi}],$$

where $R_1 = \rho_g T(w_g)^{1-\alpha} + (1 - \rho_g)T(w_b)^{1-\alpha}$, $R_2 = \rho_b T(w_b)^{1-\alpha} + (1 - \rho_b)T(w_g)^{1-\alpha}$, and $\phi = \beta(1 - \alpha)/(1 - \beta(1 - \alpha))$, and K is as defined in (19). The first bracketed term in (22) is positive (negative) when demand is elastic (inelastic). The second bracketed term is always positive because an elastic demand makes $R_1 > R_2$ and $\phi > 0$, while an inelastic demand makes $R_1 < R_2$ and $\phi < 0$. Thus, with an elastic demand curve, average use of x increases with increases in forecast accuracy. In contrast, average use of x declines if demand is inelastic. The latter case illustrates that more accurate weather forecasts can signal farmers that, on average, it is more profitable to use less of the supply-increasing input. The consequences of this signal on expected supply are shown next.

Changes in Expected Supply

Expected supply is given by

$$E(y) = cg(x_g)[\rho_g T(w_g) + (1 - \rho_g)T(w_b)] + (1 - c)g(x_b)[\rho_b T(w_b) + (1 - \rho_b)T(w_g)].$$

An increase in forecast accuracy can be evaluated by differentiating expected supply with respect to ρ_g, which with $g(x)$ specified as Cobb-Douglas results in

$$(23)\qquad \frac{\partial E(y)}{\partial \rho_g} = c[g(x_g) - g(x_b)][(T(w_g) - T(w_b)] + cK_2\left[g(x_g)\frac{\rho_g T(w_g) + (1 - \rho_g)T(w_b)}{\rho_g T(w_g)^{1-\alpha} + (1 - \rho_g)T(w_b)^{1-\alpha}} - g(x_b)\frac{\rho_b T(w_b) + (1 - \rho_b)T(w_g)}{\rho_b T(w_b)^{1-\alpha} + (1 - \rho_b)T(w_g)^{1-\alpha}}\right],$$

where

$$K_2 = \frac{c\beta}{1 - \beta(1 - \alpha)} A\left[\frac{\beta A^{1-\alpha}}{P_x}\right]^{\beta/1-\beta(1-\alpha)} \cdot [T(w_g)^{1-\alpha} - T(w_b)^{1-\alpha}].$$

The sign of (23) is not immediately apparent. It can be shown, however, (see the appendix) that when demand is inelastic, (23) is negative. Moreover, a sufficient condition for expected

supply to increase when demand is elastic is $\beta(2 - \alpha) - 1 > 0$.

A Numerical Example

The intuition behind the qualitative results developed above can be obtained with the use of a simple numerical example. Assume that $\rho_g = \rho_b$, $c = q = 0.5$, and $T(w) = 1 + w$, with $w_g = .2$, and $w_b = -.2$. The Cobb-Douglas portion of the production function is defined by setting $\beta = 0.5$ and $A = 2$. With this model specification, the calculated changes in *ex ante* expected profits, output, price, and input use as ρ increases from .5 (no information) to unity (perfect information) for both an elastic and an inelastic demand are presented in table 1. Demand is given by expression (9). Average use of x, expected supply, and expected profits all increase (decrease) as forecast accuracy increases when demand is elastic (inelastic). The response of expected profits is seen by noting that expected price also increases (decreases) as forecast accuracy increases when demand is elastic (inelastic).

To see what drives these results, refer to table 2, which reports the input levels and corresponding output levels under the two weather forecasts and the two weather states. Also reported in table 2 are expected output levels conditional on weather for the two demand elasticities. Conditional expected output is $E(y|w = w_g) = \rho f(x_g, w_g) + (1 - \rho)f(x_b, w_g)$, under w_g, and $E(y|w = w_b) = \rho f(x_b, w_b) + (1 - \rho)f(x_g, w_b)$, under w_b where $f(\cdot)$ denotes the production function. When $\rho = .5$, $x_g = x_b$, and the only variability in output is due to weather variation, which implies that $E(y|w = w_g) = f(x_g, w_g)$. When $\rho = 1$, there is no weather uncertainty, and again, $E(y|w = w_g) = f(x_g, w_g)$ because the probability associated with $f(x_b, w_g)$ is zero. Similarly, $E(y|w$

bad weather	1.10	1.11	1.15	1.17				

[a] Good weather is represented by w_g, and bad weather is represented by w_b. A forecast of good weather occurs when $\Pr(w = w_g) = \rho$. A forecast of bad weather occurs when $\Pr(w = w_g) = 1 - \rho$.

$= w_b) = f(x_b, w_b)$ under the two information extremes.

The implications of the behavior of these conditional output expectations can be seen in figure 1, which depicts the unconditional expected output and price for $\rho = .5$ and unity under an inelastic demand. In figure 1, y_g^p denotes output under perfect information and good weather; y_g^n, output under no information and good weather; y_b^p, output under perfect information and bad weather; and y_b^n, output under no information and bad weather. Furthermore, let P_g^p, P_g^n, P_b^p, and P_b^n denote the corresponding prices. Under the assumption that $q = 0.5$ (the two weather states have an equal chance of occurring), unconditional expected price and output are found by bisecting the rays connecting the two output/price pairs under each of the two weather information extremes. As shown in figure 1, as ρ increases from 0.5 to unity, expected output decreases from $E^n(y)$ to $E^p(y)$ and expected price decreases from $E^n(P)$ to $E^p(P)$.[4] Unconditional expected revenue declines because both expected output and expected price decrease. This decline more than offsets the decrease in expected cost, hence expected profits decline.[5]

[4] It can be shown that the relationship between $E(y|w)$ and ρ is monotonic for both weather states. Thus, the situation depicted in figure 1 holds for all values of ρ if, in figure 1, $E(y|w = w_g)$ replaces y_g^i and $E(y|w = w_b)$ replaces y_b^i, $i = p$ or n.

[5] The results reported in table 2 also illustrate the relationship between demand elasticity and supply variability. With an inelastic demand improvements in information reduce output variability. Farmers produce less when they are more confident that good weather is forthcoming and more when they are more confident that bad weather is forthcoming. With an elastic demand increases in forecast accuracy increase output variability because farmers are primarily concerned with the physical productivity effects of weather rather than the price effects. Thus, even though improvements in forecast accuracy decrease uncertainty, supply and price variability may increase.

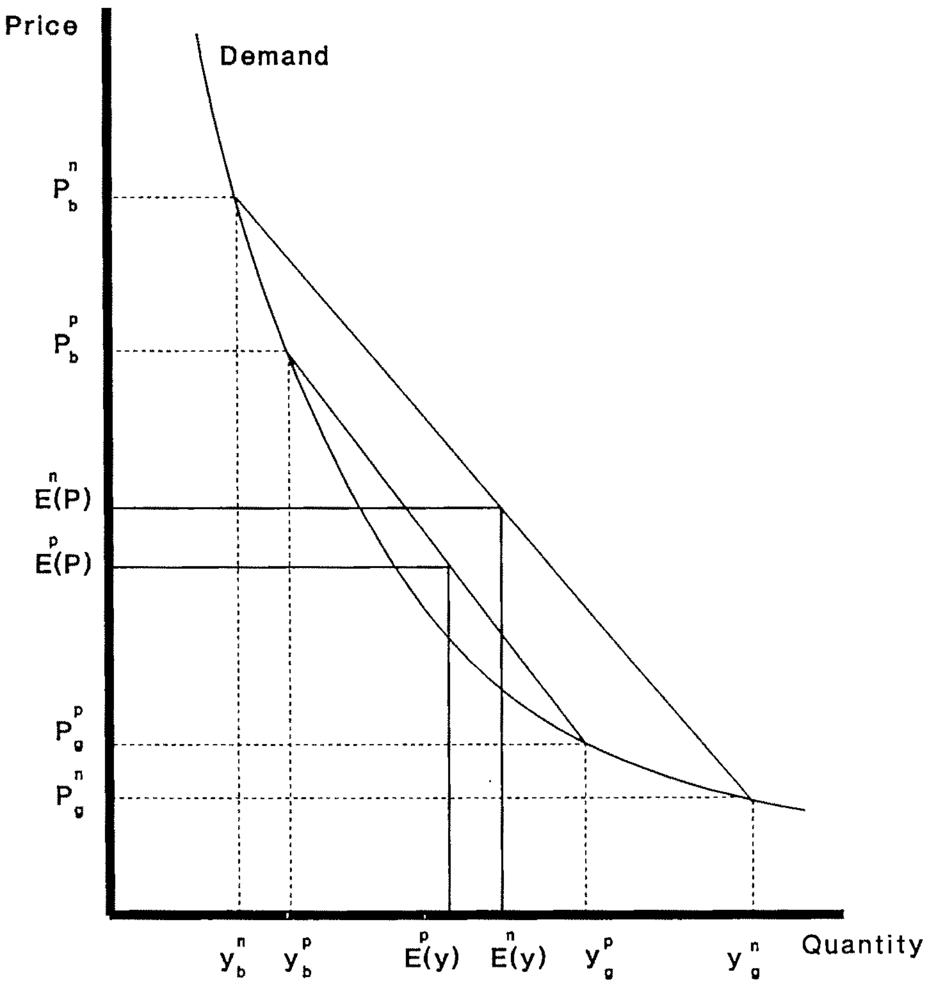

Figure 1. The supply and price effects from improved weather forecasts with an inelastic demand

Other simulation results involving a quadratic production function and a linear demand curve give further insight into the use of weather information. There were two major differences between those results and the ones reported here. First, the physical productivity effects of weather information always dominated the price effects: when good weather was forecast more accurately, more of the supply-increasing input was used; when bad weather was forecast more accurately, less of the input was used. The net effect was that expected supply increased for both inelastic and elastic demands. The second difference was that expected price and expected supply moved in opposite directions because of the restrictions imposed by the linear demand curve. Therefore, with an inelastic demand, the expected supply increase from improved weather forecasts resulted in lower total revenue, which, when combined with higher costs, meant that expected profits decreased with improvements in weather forecasts. With an elastic demand, the expected supply increase caused total revenues to increase, which more than dominated the increase in cost. Thus, the basic result that better weather information can lead to lower producer welfare is not dependent on the functional forms used here. However, the changes in input use and expected supply from better weather information are much more dependent on the particular interactions between weather variables and the marginal products of production factors.

Concluding Comments

Information is generally considered to be a supply-increasing production input and welfare increasing to producers. The argument is that producers would not use information if it did not make them better off. These two well-accepted characterizations are valid if there are no price effects from the use of the information.

Optimal input use is not only a function of physical productivity, it also depends on prices. If information signals farmers that prices will be much lower, for example, then it may be optimal to reduce the use of production factors. Price changes can also influence the value of information. The definitional truism that information is welfare increasing presumes no external effects from the use of information. One source of possible external effect is from prices. Information about the productivity of input decisions will influence prices if enough producers utilize the information to make their supply decisions. Competitive farmers have no control over prices. This lack of control creates a price externality: the aggregate effects of farmers' actions change prices, but individual farmers are too small to have a significant effect; hence, the marginal price effects are not taken into account when production decisions are made.

This paper examines an agricultural industry with many identical producers, all of whom control supply with a single variable production input. From this model, it is shown that the role of information in a production system can be quite different than is generally considered. Lave's result that producers can be made worse off from better weather information is shown to be true even when farmers know that their collective action is making them worse off. Moreover, market price effects from information can dominate physical productivity effects, particularly when demand is inelastic. When this occurs, information is a supply-decreasing production input: more accurate information signals farmers that it is more profitable for them to produce less, not more.

Calibration of Option-Based Probability Assessments in Agricultural Commodity Markets

Paul L. Fackler and Robert P. King

A method for evaluating the reliability of option-based price probability assessments is developed based on the calibration concept. Empirical tests using goodness-of-fit criteria are applied to four agricultural commodities. Results suggest that assessments in the corn and live cattle markets are reliable, but such assessments overstate the volatility of soybean prices and understate the location of hog prices.

Key words: calibration, futures, goodness-of-fit, options, probability assessment.

The initiation of trading on agricultural commodity option futures in 1984 created new risk management opportunities for market participants. This expansion in risk management alternatives directly benefits only those who trade options. As Gardner notes, however, commodity option markets can also provide useful public information about price probability distributions. Probability assessments derived from data on option premiums require only a limited amount of readily available information and can be updated easily.

For decision makers, the performance of option-based price probability assessments is an important issue. This paper focuses on one aspect of their performance: calibration or reliability (DeGroot and Fienberg; Winkler; Lichtenstein, Fischoff, and Phillips). A probability assessment method is well calibrated "if, over the long run, for all propositions assigned a given probability, the proportion that is true equals the probability assigned" (Lichtenstein, Fischoff, and Phillips, p. 307).

Calibration is important for two reasons. First, well-calibrated probability assessment methods generate reliable probability statements. Second, well-calibrated option-based probability assessments are consistent with the absence of risk premiums in options markets. Therefore, tests for calibration provide useful information about the functioning of option markets.

In the sections to follow, a theory of option pricing based on the absence of arbitrage opportunities is outlined and results from that theory are used to show how probability assessments can be derived from option premiums. The concept of calibration is then defined and statistical methods for testing the calibration of option-based probability assessments are described and used to evaluate the performance of price probability assessments for corn, soybeans, live cattle, and hogs. Implications of the findings and needs for further research are found in the concluding section.

Option Pricing Theory

Option contracts guarantee their holder the right to buy or sell a specified asset (the underlying asset) at a given price (the exercise price) on or before a given date (the expiration date). Put and call options provide the right to sell and to buy, respectively. European options allow exercise of the option only on the expiration date, while American options allow exercise any time on or before that date. An option premium is the price paid for the option contract; typically, it is payable immediately and in full.

A general theory of option pricing, based on Cox and Ross, relies on the minimal assumption that no arbitrage opportunities exist. They show that this condition is equivalent to the existence of an artificial probability distribution such that the asset price equals the stream of expected re-

Paul L. Fackler and Robert P. King are, respectively, an assistant professor in the Department of Economics and Business at North Carolina State University, and an associate professor in the Department of Agricultural and Applied Economics at the University of Minnesota.

This is Journal Article No. 16,692 of the Minnesota Agricultural Experiment Station.

turns discounted at the risk-free rate. The idea of an artificial distribution is widely applied in the finance literature. It is called the risk-neutral valuation measure (RNVM) in this paper.

To apply this notion to the pricing of options, note that the return to a European put option with exercise price x expiring at time T (the expiration date) is $\max(0, x - Y_T)$, where Y_T is the (random) price of the underlying asset at time T. If arbitrage opportunities are absent, the current price of the option, $V_p(x)$, can be written as

$$(1) \quad V_p(x) = b(T) \int_0^\infty \max(0, x - Y_T)\, dG(Y_t),$$

where $b(T)$ is the current price of a risk-free pure discount bond paying \$1 at time T, and G is the RNVM discussed above. This expression can be rearranged as

$$(2) \qquad V_p(x) = b(T)\{xG(x) - E_G[Y_T; x]\},$$

where

$$E_G[Y_T; x] = \int_0^x Y_T\, dG(Y_T)$$

is the incomplete expectation of Y_T with respect to $G(Y_T)$.

Similarly, the value of a European call option can be written as

$$\begin{aligned}(3) \quad V_c(x) &= b(T) \int_0^\infty \max(0, Y_T - x)\, dG(Y_T), \\ &= b(T)\{E_G[Y_T] - E_G[Y_T; x] \\ &\quad - x(1 - G(x))\}, \\ &= V_p(x) + b(T)\{E_G[Y_T] - x\}.\end{aligned}$$

This approach can also be used to show that the current value of an asset paying $Y_T/b(T)$ at time T is equal to y_0, the current futures price (Cox, Ingersoll, and Ross). Therefore,

$$\begin{aligned}(4) \qquad y_0 &= b(T) \int_0^\infty Y_T/b(T)\, dG(Y_T) \\ &= E_G[Y_T].\end{aligned}$$

Combining (3) and (4) yields the familiar put-call parity relationship for options on futures:

$$(5) \qquad V_c(x) - V_p(x) = b(T)(y_0 - x).$$

Given $G(Y_T)$, the value of an option can be defined. For example, if $G(Y_T)$ is log-normal with mean μ and standard deviation σ, then[1]

$$\begin{aligned}(6) \qquad V_p(x) = b(T)\{&x\Phi((z + \sigma/2) \\ &- y_0\Phi((z - \sigma/2)\},\end{aligned}$$

where $z = \ln(x/y_0)/\sigma$, and, given the symmetry of the normal distribution,

$$\begin{aligned}(7) \qquad V_c(x) = b(T)\{&y_0\Phi((z + \sigma/2) \\ &- x\Phi((z - \sigma/2)\}.\end{aligned}$$

These formulas are equivalent to the familiar option pricing formulas derived by Black (p. 177) and Gardner (p. 989).[2]

Option-Based Probability Assessments

Knowledge of the RNVM, $G(Y_T)$, which need not be log-normal, and the price of a risk-free bond, $b(T)$, is sufficient to calculate the premiums for call or put options at any exercise price. Conversely, knowledge of option premiums [and $b(T)$] can be used to infer information about $G(Y_T)$ (Breeden and Litzenberger). Suppose that $G(Y_T)$ can be reasonably well approximated by a parametric family of functions. The particular member of this family can be selected by finding the parameter values that yield predicted option premiums closest to observed market premiums.

In this study $G(Y_T)$ is assumed log-normal to simplify the analysis and facilitate comparison with other studies. A preliminary analysis using a more flexible distribution, the Burr-12 or Singh-Madalla (Singh and Madalla, McDonald), did not greatly improve the fit between predicted and actual option premiums. Under log-normality, the option valuation formulas in equations (6) and (7) have only one unobserved parameter, σ. Given an observed option premium, a value of σ can be found that yields a predicted premium exactly equal to the observed value.[3] The re-

[1]These formulas make use of the following facts (Hogg and Klugman, p. 229):

$$\begin{aligned}G(x) &= \Phi((\ln(x) - \mu)/\sigma), \\ E_G[Y_T] &= \exp(\mu + \sigma/2), \text{ and} \\ E_G[Y_T; x] &= E_G[Y_T]\Phi((\ln(x) - \mu)/\sigma - \sigma),\end{aligned}$$

where Φ is the standard normal CDF.

[2]A superficial difference between the formulas involves the $sqrt(T)$ term in Black's formulation. This difference is explained by the fact that the variance term, σ^2, used in this paper refers to the variance parameter associated with the expiration date price, which is T times the daily variance used by Black.

[3]Computationally, this involves a numerical search algorithm because no analytical solution exists. The bisection method was used in this study because it is easy to implement and reasonably fast. The evaluation of the option values also requires the numerical evaluation of the standard normal CDF. See Kennedy and Gentle (pp. 90–93) for a discussion of numerical techniques for this problem.

sulting value of σ is commonly termed the implied volatility. It is uniquely determined by the option premium, given its exercise price, the current futures price, the price of an appropriate risk-free bond, and the time until expiration, and has been used in a number of studies (e.g., Latané and Rendleman, Chiras and Manaster, Schmalensee and Trippi, Beckers).

Options typically are traded at a number of different exercise prices. Several implied volatility estimates, therefore, can be calculated for any given trading period. Options with exercise prices that are not close to the asset's current price tend to be thinly traded; thus, they may nor accurately reflect equilibrium relationships. The just-out-of-the-money option is usually the most heavily traded and is used in this study. Both the just-out put and just-out call were used to calculate implied volatilities, and the two volatility estimates were then averaged.

Given an estimate of σ the implied value of μ is given by

$$(8) \qquad \mu = \ln(y_0) - \sigma^2/2.$$

Parameters μ and σ provide a complete description of the RNVM, $G(Y_T)$.

The example in table 1 illustrates the process for generating probability assessments. The data come from the *Wall Street Journal* and include the current and expiration date futures prices, y_0 and Y_T, the just-out put and call premiums and their strike prices and the bid and ask discount rates on the appropriate T-bill. In this example, there are eight weeks (56 days) remaining until expiration. The bid and ask bond rates are combined to obtain an average rate, r, from which the bond price is calculated using $b = 1 - r*56/360$. The implied volatilities using the put and

Table 1. An Example of the Data and Calculation of the Log-Normal *RNVM*

Contract	November 1985 Soybeans
Current date	16 August 1985
Expiration date	11 October 1985
Current futures (y_0)	513.5
500 put	8.625
525 call	9.25
T-bill bid rate	7.09
T-bill ask rate	7.05
Average T-bill rate	7.07
Bond price (b)	0.989
Implied volatility from put	0.07165
Implied volatility from call	0.06942
Average implied volatility (σ)	0.07053
Implied mean (μ)	6.23876

call contracts are calculated numerically as the solution to (6) and (7). The average of these volatilities yields the implied volatility measure, σ. The "implied mean," μ, is calculated from (8).

The relationship between the artificial probability distributions generated by this process and the actual stochastic behavior of associated expiration date futures prices is an important empirical stochastic issue. If the G's reliably represent the stochasitc behavior of the associated Y_T's (i.e., if the G's are well calibrated), option-based probability assessments are a reliable, readily available source of probabilistic information. Furthermore, if the G's are well calibrated, equations (2) and (3) imply that option premiums equal the present value of the expected returns and are, therefore, an actuarially fair form of price insurance.

Generally, little can be said theoretically about the relationship between G and the stochastic behavior of Y_T. However, poor calibration of G can be identified for several reasons. First, if option writers require risk premiums because they cannot diversify away the risk of an options position, then the value of the option would be greater than under risk-neutral conditions. If G is log-normal, this condition would result in upward bias in the implied volatility. Second, risk premiums may be required by speculators in the underlying futures (see Kamara for a review). For example, if normal backwardation exists ($y_0 < E[Y_T]$), the location of G would be biased downward. Third, G may be unreliable because probability assessments of market participants are unreliable. None of these factors affect the validity of the RNVM approach to pricing options; instead, they affect the relationship between the RNVM and an objective stochastic measure of price behavior.

Poor calibration may also reflect problems with the construction of the RNVM rather than the nature of the market. For example, equations (6) and (7) strictly apply only to European options, while the options traded in the United States are American options. Failure to consider that American options are more valuable than their European counterparts (Ramaswamy and Sundaresan) could cause an upward bias in the implied volatility. However, after calculating values for both American- and European-type options, Plato concluded (p. 9) that the difference between the two for near-the-money option values is negligible. Methodological problems may also be caused by nonsynchronous option and futures prices and prices that represent nontrades, though this problem is minimized by the use of heavily traded options.

This study does not attempt to explain lack of calibration in option-based probability assessments. Rather, the goals are to examine whether such assessments are well calibrated, to describe any calibration problems, and to suggest how the assessments can be improved. The derivation of these probability forecasts is purposely simplified by not considering all possible sources of poor calibration.

The Concept of Calibration

Approximations of the RNVF derived from option premiums will not necessarily generate reliable probability statements for the expiration date futures price. An empirical examination of this issue is based on the concepts of calibration and the calibration function (Bunn, chap. 8).

To make the calibration concept more explicit, let G_i for $i = 1, \ldots, n$ be a set of probability assessments, expressed as CDFs, for a set of realizations of a random variable, Z. Given a large sample of independent assessments, G_i, and realized outcomes of Z, z_i, the probability assessment process generating the G_i is calibrated if the proportion of times $G_i(z_i)$ is less than or equal to any given value, u, on the interval [0, 1] is u. More formally, let U be a random variable on the interval [0, 1] with CDF $C(U)$, defined by $U_i = G_i(Z_i)$. The process used to generate the G_i is calibrated if U is uniformly distributed on the interval [0, 1], i.e., if $C(u) = u$ for all u on the interval [0, 1].

In this study, option-based probability assessments are the G_i. For any option-based assessment, the realized outcome, z_i, is the expiration date price of the underlying futures contract, Y_T. Evaluating the G_i at Y_T generates a CDF value, a u_i. This is illustrated by the example in table 1. The realized price associated with the assessment (the expiration date futures price) is 502. The associated CDF value, the u_i, is calculated as

$$(9)\quad \begin{aligned} u_i &= \Phi((1\text{n}(Y_T) - \mu/\sigma) \\ &= \Phi((1\text{n}(502) - 6.23876)/0.07053) \\ &= 0.3875. \end{aligned}$$

If the option-based assessment process is well calibrated, the u_i calculated in this manner from a sample of independent assessments will be uniformly distributed.

The function C, the CDF of U, is called a calibration function (Bunn; for alternate terminology see Curtis, Ferrell, and Solomon; Morris). The calibration function provides a means of transforming a noncalibrated assessment into a calibrated one. The distribution defined by the transformation $F_i(Z) = C(G_i(Z))$ will always be a calibrated distribution because, for any Z,

$$(10)\quad \begin{aligned} C(G_i(z_i)) &= \text{Prob}(G_i(Z_i) \leq G_i(z_i)), \\ &= \text{Prob}(Z_i \leq z_i). \end{aligned}$$

When the G_i are calibrated, $F_i = G_i$. When the G_i are not calibrated, the calibration function can provide insights into the nature of the problems in assessment process and their resolution.

In the example in table 1 G_i is log-normal with parameters $(\mu, \sigma) = (6.239, 0.0705)$. Suppose, however, that the options-based volatility assessment is inflated because options writers require a substantial risk premium. More specifically, suppose that dividing the volatility parameter, σ, by 2 results in calibrated assessments, and therefore F_i is log-normal with parameters $(\mu, \sigma/2)$. The calibration function associated with this case is illustrated in the upper left-hand panel of figure 1. Because the assessed distributions tend to overstate variability, U_i is more likely to fall in the center of the distribution than in its tails, resulting in an S-shaped calibration function. The original G_i and the calibrated F_i are illustrated in the upper right-hand panel of figure 1. The function C serves to calibrate G_i by shifting probability weight from the tails to the center of the distribution, thus yielding a calibrated assessment with lower variance than the original assessment.

In a second example, shown in the lower panel of figure 1, the G_i's tend to understate the mean parameter, μ, by 0.01. Such a situation might reflect normal backwardation in the underlying futures. U_i is more likely to fall above 0.5 than below it, resulting in the "J-shaped" calibration function shown in the lower left-hand panel. In this case the calibration function calibrates G_i by shifting probability weight into the right-hand tail.

These examples illustrate how the calibration function is associated with specific kinds of probability assessment problems. A straight (45°) line indicates that no such problems exist. In general, flat spots in the calibration function (parts with slope less than one) are associated with areas of the assessed distribution that receive too much weight, while steep parts are associated with areas that receive too little weight. Overassessment of the volatility, for example, places too much weight in the tail areas of the assessed distribution. The calibration function must, there-

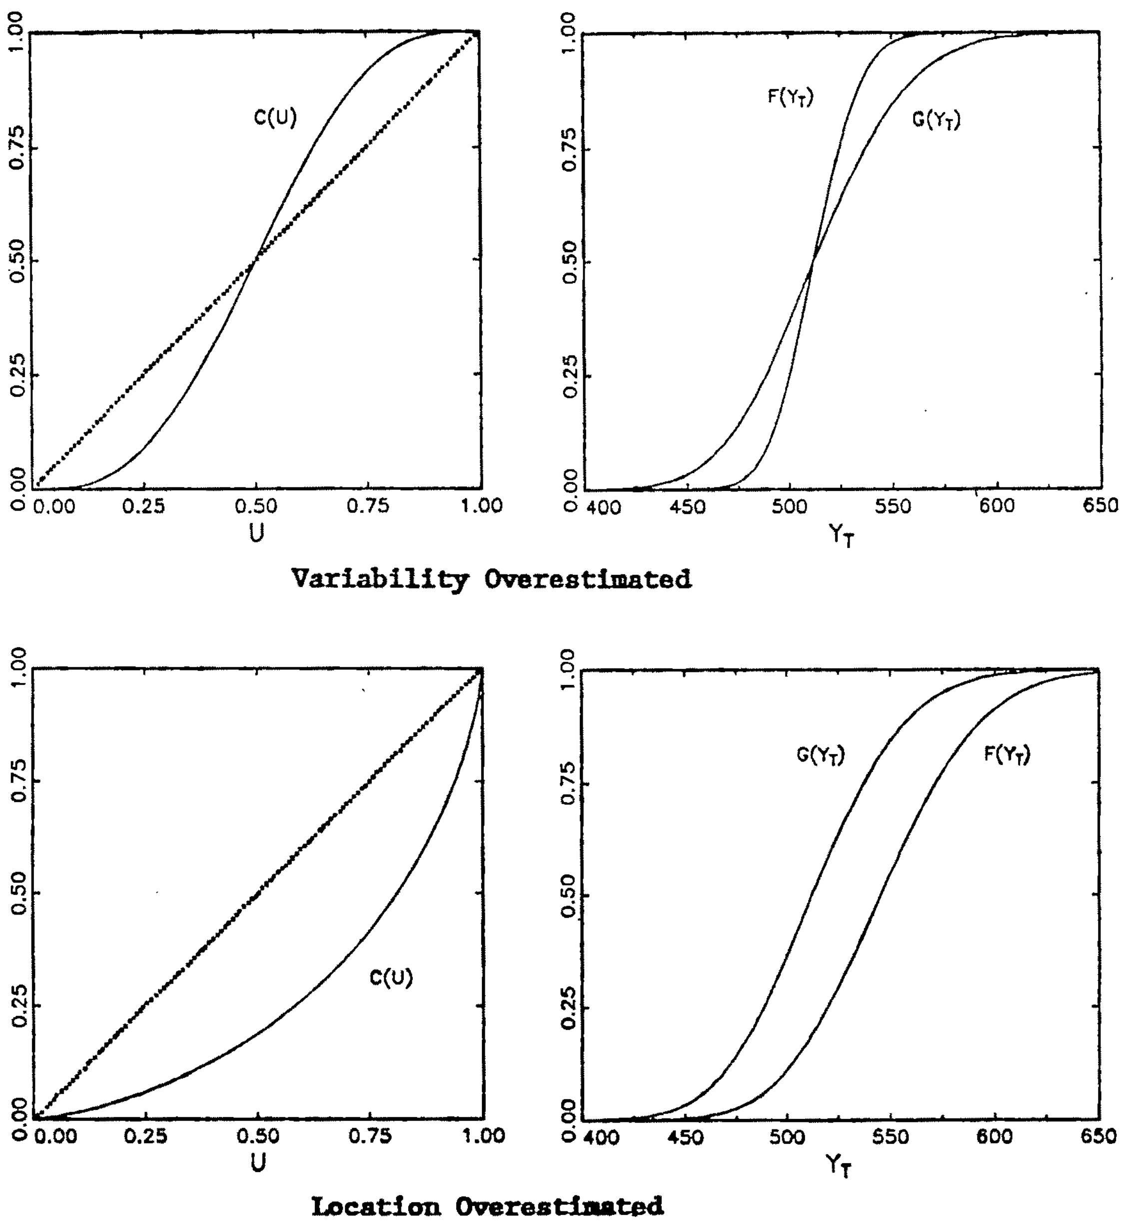

Figure 1. Examples of calibration functions: $F(Y_T) = C(G(Y_T)) = C(U)$

fore, be flat in the tails and steep in the center (S-shaped). If the assessed location is too far to the left, the calibration function must put more weight in the right tail and therefore will exhibit a flat-steep (J-shaped) pattern. Steep-flat-steep and steep-flat patterns are indicative of under-assessment of volatility and overassessment of location, respectively.

The value of the calibration function at 0.5 is a useful indictor of bias in location (median). If $C(0.5) < 0.5$ (> 0.5), more weight is in the right (left) half of the calibration function; hence, the assessed distribution is located too far to the left (right). A comparable indicator of problems in assessing dispersion is the range of the calibration function over the middle half of its domain (the interquartile range): $IQR = C(0.75) - C(0.25)$. An $IQR > 0.5$ (< 0.5) indicates that too few (many) observations fall in the tails of the assessed distribution.

Estimation of Calibration Functions

The calibration function associated with an assessment method can be estimated statistically given a random sample of values of U. A single observation on U provides no information on the reliability of an assessment process; a process can be evaluated only when patterns emerge in a sample of assessments. Furthermore, the U_t used to estimate a calibration function should be independent random variables. New option-based probability assessments can be constructed almost continuously; however, they will not necessarily yield independent U_t values because all assessments for a particular option contract share the same realized price. A random sample can be constructed by considering only one option-based assessment per futures contract and by ensuring that the time periods between trading and expiration dates do not overlap for any sample assessments.

The simplest estimator of C is the empirical CDF of a set of U_t values. After sorting the n-values of U_i in ascending order, the empirical CDF is obtained by setting $C(U_i) = i/n$. This procedure makes no assumption about the form of C. Alternatively, a parametric representation of C can be obtained by choosing a suitable functional form for C. The parametric approach offers both parsimony and ease of interpretation. Parametric forms can be fully described by a few parameters, while the empirical CDF requires the whole sample. Furthermore, if the parametric form is well chosen, specific values of the parameters will be associated with likely calibration problems in the probability assessment process. The principal disadvantage of a parametric approach is that the form chosen may not represent the calibration function well in particular cases.

The beta distribution, defined on the interval [0, 1], is a natural candidate for representing the calibration function. Its probability density function (PDF), $c(u)$, is

$$(16) \qquad c(u) = u^{p-1}(1-u)^{q-1}/B(p, q),$$

where B is the beta function (with the associated CDF denoted $B(u; p, q)$). The beta distribution is well known, flexible, and contains the uniform distribution as a special case ($p = q = 1$). The two parameters of this distribution can be easily estimated by applying maximum likelihood methods to the sample values of U_t.

The beta distribution can assume any of the four basic patterns of calibration functions discussed above (in addition to $p = q = 1$): flat-steep-flat ($p, q > 1$), steep-flat-steep ($p, q < 1$), flat-steep ($p > 1$, $q < 1$) and steep-flat ($p < 1$, $q > 1$). The condition associated with no location bias, i.e., $C(0.5) = 0.5$, occurs when $p = q$. No simple comparable condition exists for bias in dispersion. However, if p and q are nearly equal, indicating little location bias, values of p and q greater than one indicate overassessment of dispersion, while values of p and q less than one indicate underassessment.

It is possible for the calibration of an assessment process to change over time or to be dependent on conditioning variables. For example, if option premiums incorporate a risk premium which increases with the volatility of the price of the underlying asset, then the divergence between the RNVM and an objective probability measure would also increase with volatility. Furthermore, option-based probability assessments implicitly depend on the assessments made by options traders, who can learn if their assessments are unreliable. This might result in option-based assessments becoming more calibrated as an option market matures. Unfortunately, the recent opening of agricultural option markets limits available data; therefore, a simple unconditional calibration function is estimated for each sample examined in this study.

Tests of Calibration

An examination of whether observed departures from calibration are statistically significant can be based on goodness-of-fit tests for uniformity on [0, 1]. Three approaches to testing for uniformity are used in this study, with the main focus on detecting potential problems in the assessment of location and dispersion.

The first test is based on the percentage of the u_t values lying within an interval of length 0.5 on the interval [0, 1]. Under the null hypothesis, the chance that a realization of U will lie in any such range is 50%. The interval [0, 0.5] provides information on bias in location (median), while the interval [0.25, 0.75] provides information on bias in the dispersion (interquartile range). This test is a variant of the sign test, which rejects the null hypothesis if the percentage falling into such an interval is either too large or too small relative to a binomial distribution in which the probability of a "success" is 0.5.

Nonparametric goodness-of-fit tests based on the empirical CDF comprise the second approach. Stephens discusses and evaluates a

number of such tests, including the familiar Komolgorov test. Each of the tests varies in relative power against alternative hypotheses. The Watson U^2 and the Cramer-von Mises tests appear to be relatively powerful against alternatives associated with nonuniform dispersion and location, respectively. Further power tests by Quesenberry and Miller support this finding and indicate that the Watson test is a good candidate for a single omnibus test of uniformity.

A third approach uses the maximum likelihood parameter estimates of the fitted beta calibration function to construct a likelihood ratio statistic for the hypothesis that $p = q = 1$, the parameter values for the uniform special case. Because the loglikelihood of the uniform distribution is always equal to zero, the likelihood ratio statistic is twice the maximum likelihood. This test statistic has an asymptotic chi-square distribution with two degrees of freedom. Monte Carlo simulation results performed by the authors suggest that the test statistic should be multiplied by a small sample correction factor of $(1 + 1/n)$, where n is the sample size. Further simulation results indicate that this test statistic compares favorably in power to the nonparametric tests examined by Stephens.

Testing the Calibration of Option-Based Probability Assessments in Agricultural Markets

Option trading for soybeans and cattle began in October 1984, while trading for corn and hogs began in February 1985. The options are written on futures contracts. For cattle and hogs, those futures contracts expire in February, April, June, August, October, and December. For soybeans, they expire in January, March, May, July, September, and November; for corn they expire in March, May, July, September, and December.[4] For all of these commodity options, trading ends on a Friday one to two business weeks prior to the beginning of the futures contract delivery month. The expiration date futures price is taken to be the close price on the last trading date of the options. Samples of size 15, 20, 20, and 18 (July 1985–May 1988, March 1985–May 1988, Feb. 1985–Apr. 1988, and June 1985–Apr. 1988) were used for corn, soybeans, cattle, and hogs, respectively. Futures prices and option premiums for corn and soybeans prior to 1986 are from Chicago Board of Trade tapes. All other data are from the *Wall Street Journal*.

Probability assessments for each commodity were generated on dates eight and four weeks prior to expiration. These assessments were used to construct two samples (per commodity) of realized CDF values, i.e., of U_i. The CDF values within each sample can be viewed as independent random variables because the periods between assessment and expiration dates do not overlap. Thus, each sample can be used to test for calibration. The two samples for each commodity are not independent because the period between assessment and expiration dates of the four-week assessment is always encompassed by that of the eight-week assessment. Thus, it is inappropriate to pool the samples. However, presenting the results for both samples does indicate possible changes in the calibration of option-based assessments as the forecast period changes.

CDF values associated with the expiration date futures price for each of the eight samples were used to construct the empirical and fitted beta calibration functions shown in figure 2.[5] The calibration functions estimated by the two methods have similar shapes, supporting the use of the beta distribution as a parametric form for representing calibration functions. The main exceptions are in the eight-week samples for corn and cattle, both of which have empirical, but not beta, calibration functions that exhibit flat areas in the center portion of the [0, 1] interval. One should suspect therefore that, in these cases, test results based on the beta distribution may be in conflict with those based on nonparametric methods.

The shapes of the calibration functions vary considerably across these markets. For corn and cattle the calibration functions are difficult to characterize and are not consistent between the eight- and four-week samples. The eight-week sample for corn has a steep-flat-steep pattern, while the four-week sample has a flat-steep-flat pattern. These patterns are roughly associated with problems in the under- and over-assessment of dispersion. The eight-week cattle sample has a steep-flat-steep pattern, while the four-week sample has a flat-steep pattern. For soybeans, however, both samples clearly exhibit a flat-steep-

[4] August soybean and July hog contracts are also traded. However, these contracts were not used so that two-month periods between expiration dates could be maintained, thereby eliminating the possibility of overlapping forecast periods. The expiration dates are spaced two or three months apart in the corn market.

[5] For ease of interpretation, the empirical calibration function is presented as a piecewise linear function that linearly interpolates the points $\{u_i, (i - 0.5)/n\}$, with u_i sorted and using (0, 0) and (1, 1) as endpoints.

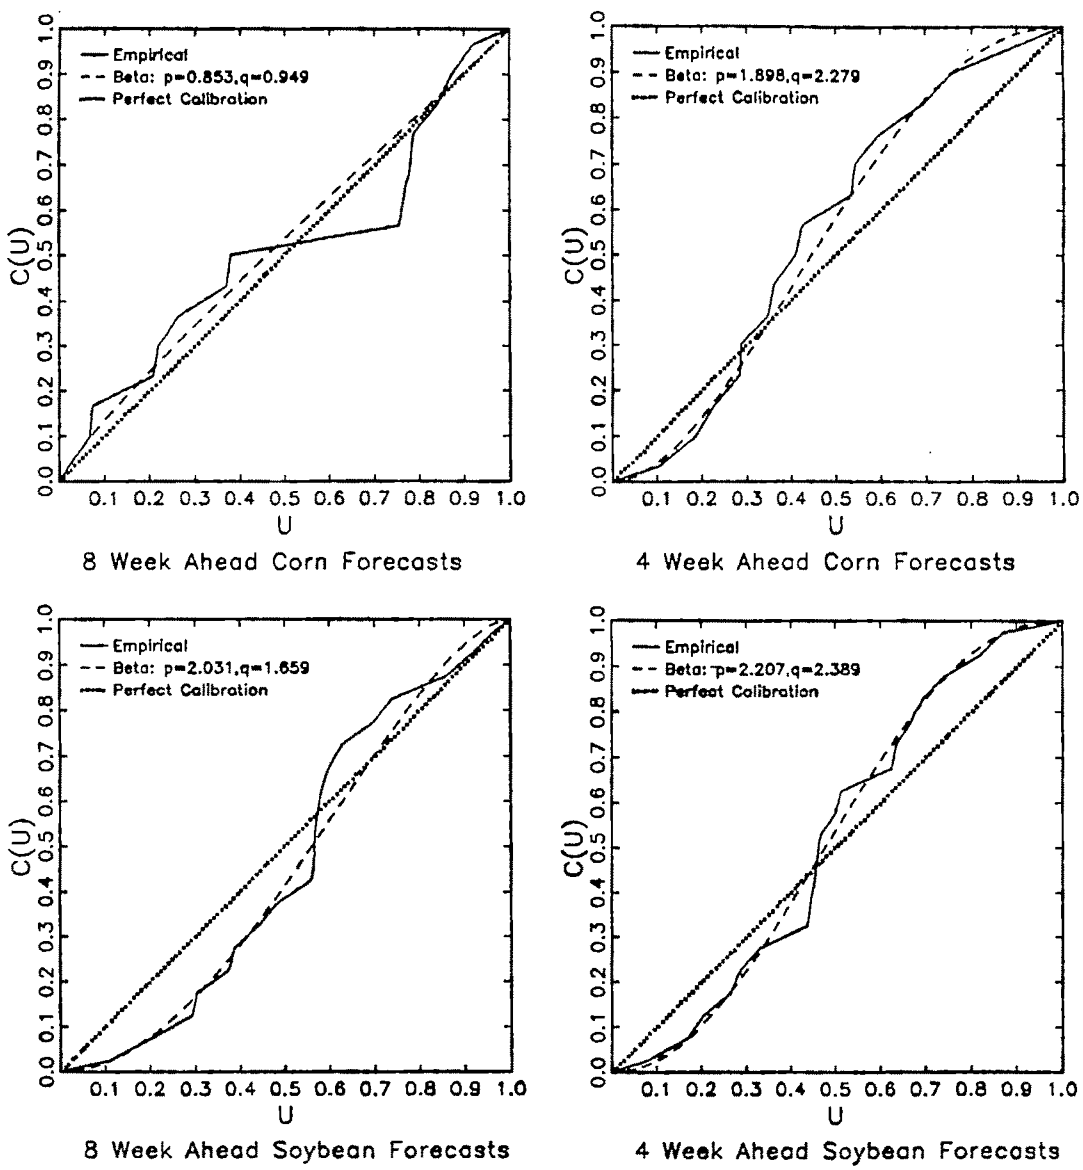

Figure 2. Empirical and beta calibration functions

flat pattern, while for hogs both exhibit a flat-steep pattern. These patterns suggest that probability forecasts in the soybean and hog markets exhibit overassessment of dispersion and underassessment of location, respectively.

Statistical results in table 2 largely confirm the graphical results. The sign test results show the percentage of observations in each sample falling into the [0, 0.5] and [0.25, 0.75] intervals, as well as the associated p-values for the two-sided test. Tests on the first of these intervals suggest problems in assessing location in the four-week hog sample, and, weakly, in the four-week cattle sample. The second of these intervals suggests problems in assessing dispersion in both soybean samples and both corn samples, although only weakly in the four-week corn case. For corn, however, the eight-week sample has too few observations in the [0.25, 0.75] interval, while the four-week sample has too many.

These results are generally consistent with those of the nonparametric Watson and Cramer-von Mises tests. No assessment problems are indicated for corn and cattle. On the other hand, the Watson test rejects the null hypothesis in both

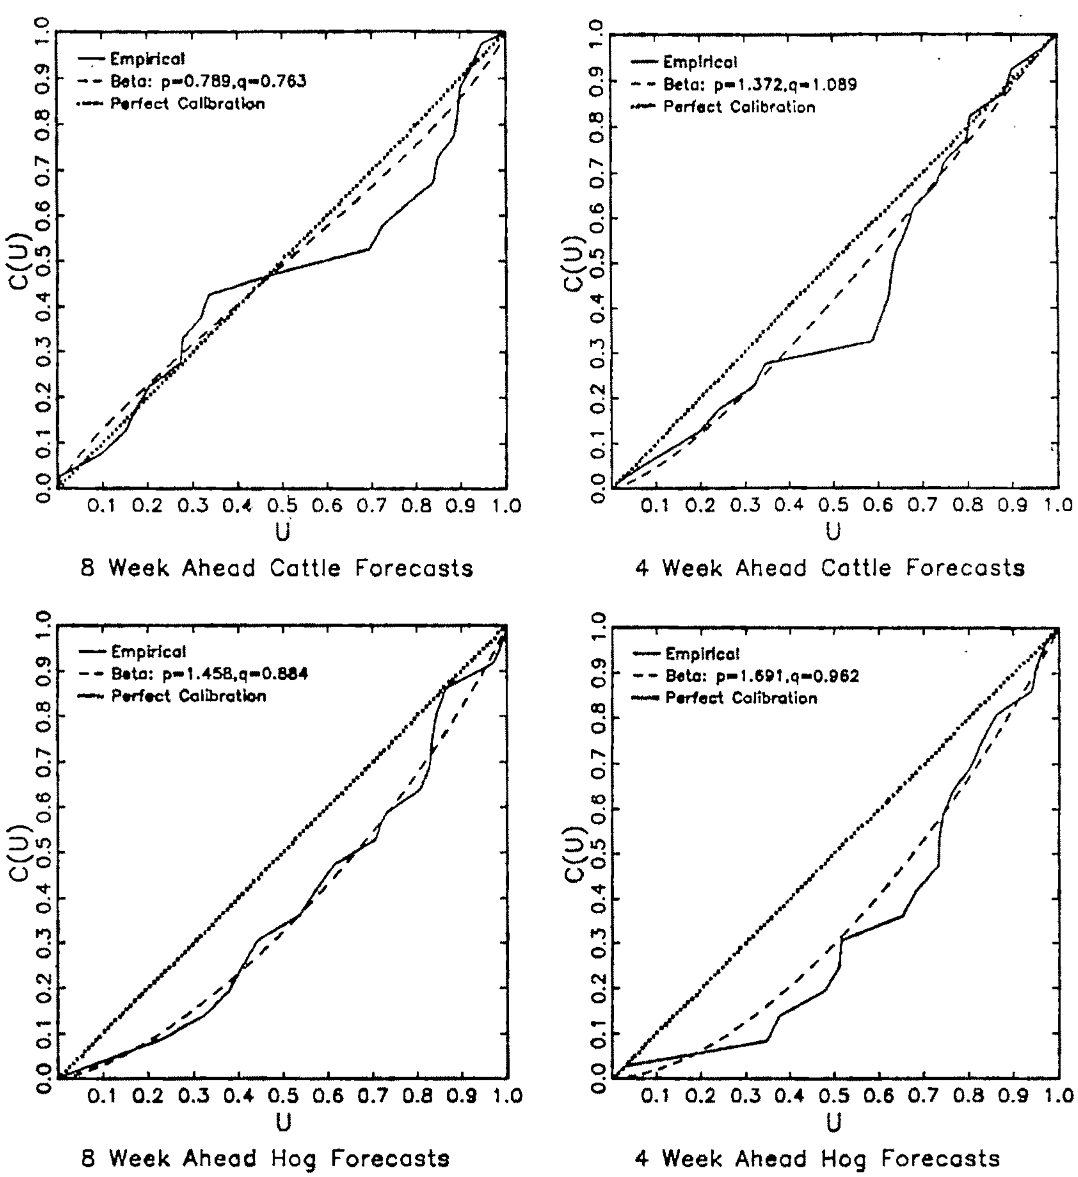

Figure 2. Continued

soybean samples. For hogs both tests reject the null hypothesis at the 0.05 significance level in the four-week case, while the null hypothesis is rejected at the 0.15 level by the Cramer-von Mises test in the eight-week sample.

The parametric (beta distribution) test results provide only weak evidence of noncalibration in the four-week sample in the corn market and none in the cattle market. Calibration problems are indicated in both soybean and hog markets, with the problems in both cases most evident in the four-week samples.

Taken together, these results suggest calibration problems in option-based probability forecasts for both the soybean and hog markets. For soybeans these problems involve overassessment of dispersion; for hogs they involve underassessment of location, although the evidence for this is not quite as strong.[6] The corn market results are somewhat ambiguous, but they do not

[6]An examination of hog futures prices in the period 1976–84 (prior to options trading) reveals no evidence that the probability of an up or down movement was other than 50% at either the 4- or 8-week horizon. The results for the 1985–88 period therefore reflect recent developments in this market or are attributable to sampling error.

Table 2. Calibration Test Results

Samples	Sign Tests (%) [0, 5]	Sign Tests (%) [.25, .75]	Cramer-von Mises W^2	Watson U^2	Beta LR
Corn					
8-Week	53.3 (.607)[a]	20.0 (.035)	0.97	.113	0.277 (.871)
4-Week	60.0 (.302)	66.7 (.118)	.148	.117	4.398 (.111)
Soybeans

Hogs					
8-Week	33.3 (.238)	50.0 (.815)	.320*	.065	3.585 (.167)
4-Week	22.2 (.031)	55.6 (.481)	.675#	.187#	4.664 (.097)

[a] p-values are shown in parentheses; asterisk indicates significant at the 0.15 level; @ indicates significant at the 0.10 level; # indicates significant at the 0.05 level.

suggest that option-based probability forecasts exhibit a consistent noncalibration pattern. Instead, a change from under- to overassessment of dispersion is indicated when the forecast horizon is changed from eight to four weeks. Without further study, this apparent calibration problem is perhaps best attributed to sampling fluctuation.

For those markets with calibration problems, the option-based assessments can be transformed using the estimated calibration function (either the nonparametric or the beta). To illustrate, consider the probability distribution associated with the July 1988 soybean futures at the expiration of the associated option (17 June 1988). On 22 April 1988, the log-normal option-based assessment was $G(Y_T) = \Phi((\ln(Y_T) - 6.508)/0.08174)$. However, given the relevant calibration function (8-week soybean) shown in figure 1, an improved assessment could be obtained by using $F(Y_T) = B(G(Y_T), 2.031, 1.659)$.

Table 3 contains a comparison of selected percentiles of these two distributions. The calibrated distribution has shifted the median up by nearly 8.5¢ and reduced the interquartile range by nearly 30% from 73.0¢ to 52.5¢. Because of unanticipated drought conditions, the realized expiration date price of 971.5 was in the extreme right-hand tail of both distributions.

Table 3. A Comparison of Selected Fractiles for a Noncalibrated and a Calibrated Probability Assessment

U	Noncalibrated ($G^{-1}(U)$)	Calibrated ($F^{-1}(U)$)

Concluding Comments

This paper focuses on methods for assessing and evaluating price probability distributions based on options market data. The recent development of agricultural option markets makes this a timely topic, but it also allows for only a preliminary evaluation of these methods. Nonetheless, the applications in the four commodity markets demonstrate the potential of the methods. Option premiums can be used to provide information on price probability distributions, yielding a complete assessment of the stochastic nature of prices that is easily obtainable at low cost and that can be regularly updated.

The results of this paper suggest that there are differences among markets in the reliability of option-based probability assessments. Little evidence was found of any systematic assessment problems in the corn and live cattle markets. However, the results suggest that option-based assessments of price distributions overstate the variability of soybean prices and underpredict the location of hog prices.

The results presented here are preliminary, pending maturity of the options markets under study. However, they present both a framework for the study of the reliability of probability assessments and demonstrate the ability of the statistical tests used to both support and reject the null hypothesis of calibration. Further research could usefully explore the causes of apparent noncalibration, particularly in the soybean market. It would also be useful to compare the reliability of option-based assessments with other assessment methods. Clearly, options markets provide a rich data base for further study.

The Reaction of Live Hog Futures Prices to USDA *Hogs and Pigs Reports*

Phil L. Colling and Scott H. Irwin

Strong concerns about how efficiently live hog futures prices react to U.S. Department of Agriculture *Hogs and Pigs Reports* have been raised by livestock producer groups. Using market survey data, direct tests of the efficient markets hypothesis are performed for the live hog futures market. Two-limit tobit models account for institutional price limits. Results support the efficient market hypothesis in that live hog futures prices (*a*) do not react to anticipated changes in reported information, (*b*) do react significantly and in the expected direction to unanticipated changes in reported information, and (*c*) generally adjust to unanticipated information on the day following release of the reports.

Key words: efficient market hypothesis, expected information, survey data, two-limit tobit model, unanticipated information.

A market is efficient if prices discovered in that market fully reflect all available information (Fama). Therefore, in an efficient market, price changes should occur only as the result of new information. Old information is already incorporated into price and should therefore lead to no further price changes. In addition, price changes as the result of new information should occur rapidly, perhaps instantaneously.

Prices on various markets often react sharply after the release of new major information. For example, stock prices often change substantially after the release of reports on trade, inflation, unemployment, and capacity utilization. Commodity futures prices often change after the U.S. Department of Agriculture (USDA) releases various crop and livestock reports. However, prices sometimes do not change or change only slightly after the release of reports. In such cases, the market may have accurately anticipated the report information. In an efficient market, price changes should reflect differences between market expectations of new information and the actual information upon release.

A controversial example of the release of important new information is the quarterly USDA *Hogs and Pigs Report,* where estimates of the size of the total hog inventory, breeding and market hog inventories, and farrowing intentions are reported. Livestock producer groups have voiced strong concerns that live hog futures prices do not react efficiently to the information contained in the *Hogs and Pigs Reports*. The purpose of this paper is to test the hypothesis of market efficiency for the live hog futures market.

Previous studies of the effect of *Hogs and Pigs Reports* on live hog futures prices (USDA; Miller; Hoffman; Hudson, Koontz, and Purcell) do not use survey data of market expectations to distinguish between anticipated and unanticipated information. Hence, direct tests of market efficiency are not possible. In this study, survey data of market analysts' expectations of changes in breeding and market hog inventories are used to distinguish between anticipated and unanticipated information. The survey data are tested to determine their appropriateness with regard to unbiasedness, efficiency, and forecast performance. Then, maximum-likelihood estimation of two-limit tobit models and likelihood-ratio tests are used to determine if anticipated and unan-

Salaries and research support were provided by state and federal funds appropriated to the Ohio Agricultural Research and Development Center, Ohio State University Journal Article No. 127–89.

The authors are indebted to Doug Harper and Anthony Dryak for providing the market expectation survey data and to Cameron Thraen for his methodological suggestions and computer assistance. Comments by Michael Hudson, Leroy Hushak, Bruce Sherrick, Carl Zulauf, and Dennis Henderson on a previous draft of this paper are also gratefully acknowledged.

ticipated information has subsequent effects on prices after the report release. The possibility of predictable price patterns up to four days after the reports is also examined.

Throughout the paper, reference is made to three categories of information. These include expectations, report, and unanticipated information. Expectations information refers to the prereport expectations of reported information. This is sometimes referred to as "anticipated" information. Report information refers to the information contained in the USDA *Hogs and Pigs Reports*. Unanticipated information refers to the difference between expectations and report information.

Review of Previous Research

Previous studies of the effects of USDA reports on commodity futures prices provide only indirect evidence to support the efficient markets hypothesis. Like most studies of stock price behavior (i.e., Fama et al., Castanias), they observe the behavior of futures prices around the announcement date. Gorham studies the changes in soybean, wheat, and corn prices after the releases of monthly USDA crop production forecasts. He observes the changes in prices after the announcements, given the differences in the most recent forecasts and the forecasts of the previous month. Results indicate that changes in production harvest forecasts, and to a lesser degree wheat production forecasts, have a significant effect on subsequent price changes. Because changes in soybean production forecasts do not have a significant effect on price, he concludes that traders are better able to anticipate forecasts for soybean production as compared to corn or wheat production. Fackler, comparing the variance of price changes of corn and soybean futures after the release of reports to all other times, finds that variance is 2.5 times greater after the release of those reports for both contracts. This indicates that price adjustments occur in response to the reports supporting the notion of market efficiency.

Miller, USDA (1977), and Hoffman study the short-term behavior of live hog futures prices before and after the release of USDA *Hogs and Pigs Reports*. Miller examined price changes one day before and after the release of reports, whereas USDA (1977) and Hoffman used weekly averages of prices before and after the release of the reports. The results of the three studies suggest that futures prices generally react quickly to new information, but some exceptions are noted, especially for deferred contracts. Hudson, Koontz and Purcell study longer-term behavior of live hog futures prices by using prices twenty days before and after the release of *Hogs and Pigs Reports*. They concluded that live hog futures prices "adjust to new information in the *Hogs and Pigs Reports* rapidly and, in general, move in the appropriate direction" (p. 36). However, they also argue that the market is efficient but that it lacks sufficient information. Like most studies of stock market behavior, the above studies do not discriminate between anticipated and unanticipated components of new market information. It also appears that price limits are not accounted for, which would bias the results.

Barnhart's study is unique in that survey data of market participants' expectations of changes in fundamental variables are used to construct measures of anticipated and unanticipated changes in information. He estimates the effects of anticipated and unanticipated changes in the money supply, the Federal Reserve discount and surcharge rates, the consumer price index, the producer price index, the unemployment rate and the U.S. industrial production index on futures price changes for several commodity futures contracts. The sample runs from 1977 through 1984 and is broken into three subsamples to account for different monetary policy regimes over the period. For some contracts, it is found that prices do not adjust immediately to unanticipated information. This is possibly attributable to transactions costs, information costs, or institutional characteristics. It is unclear as to whether price limits are considered.

Theoretical Considerations

The following general model (Pearce and Roley) is used to investigate the response of live hog futures prices to anticipated and unanticipated information and to test basic hypotheses of efficient markets:

$$\Delta FP_t = a + x_t^u{*}b + x_t^e{*}c + \sum_{i=1}^{m} x_{t-i}^u{*}d + \mu_t, \tag{1}$$

where ΔFP_t is the percent change in closing futures prices from day $t - 1$ to day t; x_t^e is a ($1 \times k$) vector of expected informational components given information known on the close of trading on day $t - 1$; x_t^u is a ($1 \times k$) vector of

unanticipated informational components, derived as the difference between announced components, x_t^a, and expected components, x_t^e; x_{t-i}^u is a $(1 \times k)$ vector of unanticipated components occurring i days prior to day t; μ_t is a stochastic error term; a is a constant and b, c, d_i are $(k \times 1)$ vectors of parameters. If market expectations are rational, then

$$(2) \qquad x_t^e = E(x_t^a | \Omega_{t-1}),$$

where x_t^a is a $(1 \times k)$ vector of announced information, and Ω_{t-1} is the information set on the close of day $t - 1$ in order that $(x_t^a - x_t^e)$ is uncorrelated with Ω_{t-1}.

Under the efficient markets hypothesis, each element of c should not be significantly different from zero because all known information, Ω_{t-1}, should be reflected in the previous day's closing futures price, FP_{t-1}. Also, each element of d_i should not be significantly different from zero because nonzero elements would imply that futures prices adjust slowly to new information. Therefore, if the market is efficient, model (1) becomes

$$(3) \qquad \Delta FP_t = a + x_t^u{*}b + \mu_t,$$

and model (3) should not be rejected in favor of equation (1). If this holds, then equation (3) becomes the relevant model to determine the effect on futures price changes after unanticipated information is realized.

Given the nature of the major information released in the USDA *Hogs and Pigs Reports*, the independent variables for this study ideally would include anticipated and unanticipated changes in breeding and market hog inventories as well as farrowing intentions. However, survey data are unavailable for anticipated changes in farrowing intentions. Hence, the model for this study includes only anticipated and unanticipated changes in breeding and market hog inventories. However, correlation coefficients for actual changes in breeding hog inventories and farrowing intentions are quite high. The correlation coefficient for actual changes in breeding hog inventories and farrowing intentions during the quarter including the month of and the two months following the survey date is 0.94. The correlation coefficient for actual changes in breeding hog inventories and farrowing intentions during the quarter four to six months after the survey date is 0.88. This suggests that correlations between unanticipated changes in those categories might also be high. Therefore, much of the impact of unanticipated changes in farrowing intentions likely is captured by unanticipated changes in breeding hog inventories.

Based on the specified model, anticipated information concerning changes in breeding and market hog inventories should be fully reflected in live hog futures prices before the release of the *Hogs and Pigs Reports*. Therefore, after the reports are released, anticipated information should lead to no further price changes. Price changes should only reflect new information associated with the reports.

In general, the relationship between live hog futures prices and unanticipated changes in hog inventories should be negative. That is, if a report shows that hog inventories are higher than expected just before the release of the report, or that supply is higher than expected, then prices should drop after the release of the report, and vice versa. Prices should adjust rapidly after the release of reports.

More specifically, prices of nearby futures contracts should be more responsive to unanticipated changes in market hog inventories because this unanticipated supply will be ready for market in the near term. Contracts which expire at a time approximately equal to a hog production cycle (approximately eight to ten months) should be more responsive to unanticipated changes in breeding hog inventories. This would reflect unanticipated changes in the potential nearby pig crop which would be ready for market at that time. It is somewhat unclear how distant contracts, beyond a production cycle, would be affected by surprises in breeding and market hog figures. However, the negative relationship between unanticipated figures and futures prices for those contracts should exist.

Data

Closing live hog futures prices are collected on the days the *Hogs and Pigs Reports* are released, along with those one through four trading days after and two days prior to the release of the reports. Various time horizons of live hog futures contracts are defined corresponding to the approximate number of months from the time the *Hogs and Pigs Reports* are released until the contracts expire. Because futures contracts do not exist for every month of the year, it is impossible to obtain a perfectly balanced design. Five time horizons are defined, with the nearby time-horizon contracts expiring approximately two to three months after the report releases and with the distant time-horizon contracts expiring

Table 1. Futures Contracts Used for Each Time Horizon

	Quarterly Report			
Time Horizon	March	June	Sept.	Dec.
1	June (3)	Aug. (2)	Dec. (3)	Feb.+[a] (2)
2	July (4)	Oct. (4)	Feb.+ (5)	Apr.+ (4)
3	Oct. (7)	Feb.+ (8)	Apr.+ (7)	July+ (7)
4	Feb.+ (11)	Apr.+ (10)	July+ (10)	Oct.+ (10)
5	Apr.+ (13)	June+ (12)	Oct.+ (13)	Dec.+ (12)

[a] A (+) indicates that the corresponding contract month is used for the year following the *Hogs and Pigs Reports*. Numbers in parentheses are the approximate number of months after the report release to the expiration of the futures contract.

in about twelve to thirteen months. Table 1 lists the futures contracts used for each time horizon along with the corresponding number of months after the release of the reports until expiration of the contracts. The various time horizons allow for comparison of the specific effects of anticipated and unanticipated changes in breeding and market hog inventories across a wide spectrum of futures contracts.

An average of market analysts' expectations is used as the proxy for market expectations of reported changes in breeding and market hog inventories from year-ago levels. Analyst expectations are collected in a survey by Futures World News. Specifically, fifteen analysts on average are canvassed regarding their expectations of changes in total, breeding, and market hog inventories. Survey results are released after the close of trading two days before the USDA *Hogs and Pigs Report* is announced. Subsequent actual changes in ten-state breeding and market hog inventories from year-ago levels are published in quarterly USDA *Hogs and Pigs Reports*.[1] The USDA report is released after the close of trading on the announcement day. The sample period runs from the September 1981 through the June 1988 reports, providing twenty-eight observations.

To examine the suitability of the market survey data with respect to unbiasedness, efficiency, and forecast performance, four tests are performed, following the methodology set forth by Pearce and Roley. If these tests are passed, then the data are deemed appropriate for testing the efficient markets hypothesis. The first test is designed to determine if the survey data are unbiased. No systematic bias should be revealed if the survey data are rational. The following models are estimated using ordinary least squares:

(4) $$BRD_t^a = \beta_0 + \beta_1 BRD_t^e + \mu_t \text{ and}$$

(5) $$MKT_t^a = \beta_0 + \beta_1 MKT_t^e + \mu_t$$

where *BRD* denotes changes in breeding hog inventories from the year-ago level, *MKT* denotes changes in market hog inventories from the year-ago level, a superscript *e* denotes expected information, a superscript *a* denotes actual information, and a subscript *t* denotes the report release date. A paired *F*-test is performed to test the null hypothesis H_0: $\beta_0 = 0$, $\beta_1 = 1$ for both breeding and market hogs. The marginal significance levels reported in table 2 indicate that unbiasedness can not be rejected.

Because important new information could affect live hog futures prices in the two days between the release of the survey of market analysts and the release of the *Hogs and Pigs Reports,* a second test of unbiasedness is conducted. Following Pearce and Roley, new information is assumed to be reflected by the percentage change in closing futures prices from the release date of the market analysts' survey to the release date of the USDA *Hogs and Pigs Reports*. Hence, the following models are estimated using ordinary least squares:

(6) $$BRD_t^a = \beta_0 + \beta_1 BRD_t^e + \beta_2 \Delta FP_t^i + \mu_t \text{ and}$$

[1] Prior to the June 1982 USDA *Hogs and Pigs Report*, quarterly data were based on 14 states. Therefore, in our sample, the first three observations are based on 14-state data. To determine if this biased the results, all estimations were reestimated with the first three observations deleted. The results were virtually identical, indicating that no substantial bias exists. Results presented are those of the full sample period (28 observations).

Table 2. Tests of the Unbiasedness of the Survey Data

Report Figure of	Coefficient Estimates β_0	β_1	Summary Statistics[a] Adj R^2	S.E.	D-W	H_0: $\beta_0 = 0$, $\beta_1 = 1$ $F(2, 26)$	M.S.[b]
Breeding hogs	−.908 (.617)	.997 (.089)	.82	3.15	1.95	1.152	.332
Market hogs	.332 (.392)	.950 (.054)	.92	2.00	2.09	1.075	.356

Note: Standard errors of the estimated coefficients are in parentheses.
[a] Adj R^2 is adjusted R^2; S.E. is standard error; D-W is Durbin-Watson d.
[b] M.S. is marginal significance level.

$$(7) \qquad MKT_t^a = \beta_0 + \beta_1 MKT_t^e + \beta_2 \Delta FP_t^i + \mu_t,$$

where ΔFP_t^i is the difference between the natural logarithms of the closing futures prices on the release dates of the market analysts' survey and the USDA report for time horizon i ($i = 1, \ldots, 5$). This price change is simply a proxy for new information. All other variables are defined for equations (4) and (5). If either of the β_2 coefficient estimates from (6) and (7) are significantly different from zero, this would indicate that new information consistently enters the market in a nonrandom fashion between the release of the survey and the report. In such a case, the survey data of market expectations could be consistently biased. The data then would need to be adjusted to reflect that bias. In none of the ten estimated equations is the β_2 coefficient significant or the β_0 and β_1 coefficients substantially changed from estimates presented in table 2.[2] Thus, on average, no new important information is released between the survey and the USDA report. As a result, there is no need to adjust the survey expectations to reflect a revised market expectation.

In the third test the efficiency of the survey data is tested by estimating the following models:

$$(8) \qquad BRD_t^u = \beta_0 + \beta_1 BRD_{t-1}^a + \mu_t, \text{ and}$$

$$(9) \qquad MKT_t^u = \beta_0 + \beta_1 MKT_{t-1}^a + \mu_t,$$

where a superscript u denotes unanticipated information, computed as the difference between changes reported in the *Hogs and Pigs Reports* and analysts' survey data. Using the final prediction error (FPE) criteria of Akaike, one lag is chosen for both models in which a total of four lags are allowed to enter. Pearce and Roley, citing Modigliani and Shiller, note that "the basic notion behind this concept is that if announced data are generated by an autoregressive process, the market's expectation should be generated by the same process" (p. 57). Lag coefficients should not be significantly different from zero. As table 3 indicates, the null hypothesis is not rejected.

The fourth test determines if forecasting autoregressive models can outperform the survey data. The following autoregressive models are estimated:

$$(10) \qquad BRD_t^a = \beta_0 + \beta_1 (BRD_{t-1}^a) + \beta_2 (BRD_{t-2}^a) + \mu_t, \text{ and}$$

$$(11) \qquad MKT_t^a = \beta_0 \text{ and } \beta_1 (MKT_{t-1}^a) + \beta_2 (MKT_{t-2}^a) + \mu_t.$$

Again, the FPE criteria is used to select the number of lags where up to four lags are allowed to enter. From table 4, the forecast root mean square error is lower for the survey data than for the autoregressive models for both breeding and market hogs, indicating that the survey data is a better forecaster than the models. The results are especially significant when it is noted that the model forecast errors are generated in-sample and the survey forecast errors are generated *ex ante* out-of-sample. As the forecasting accuracy of univariate time-series models is well known, this raises the interesting question of whether model-based forecasts of hog inventory categories (Blanton et al.) are economically valuable.

Based on the previous four tests, it is concluded that the survey data have desirable properties and are appropriate for direct tests of the efficient markets hypothesis. But before moving on to such tests, an important econometric problem must be addressed.

[2] These results are available from the authors upon request.

Table 3. Tests of the Efficiency of the Survey Data

Report Surprise in:	Coefficient Estimates		Summary Statistics[a]			Test H_0: $\beta_1 = 0$

[d] Survey data

Econometric Model

A problem encountered in this research deals with institutional price limits of the Chicago Mercantile Exchange. Live hog futures prices are allowed to move by no more than $1.50 per hundredweight during a trading day from the previous day's closing price. If the price hits the limit, trades may still take place at that price. However, if the closing price is at the limit, this indicates an imbalance in supply and demand, and hence the closing price is not an equilibrium free market price. As a result, daily closing prices may be inappropriate for testing market efficiency and predicting price changes after report releases given unanticipated information. For example, if ordinary least square is applied to equation (3), the estimated coefficients of b would be biased toward zero because the dependent variable can take on only limited values or values between the limits. In this study, closing prices on days after the reports are limit moves for at least one-half of the twenty-eight observations for all five time horizons. Therefore, alternative measurement techniques must be examined in order to examine and test models (1) and (3).

To deal with this problem, maximum-likelihood estimation of the two-limit tobit model as presented by Rosett and Nelson is used to estimate parameters and test hypotheses. This allows for estimates of true price changes in light of price limits and the limited-dependent variable problem. Maddala notes that when the dependent variable is truncated on two sides but is allowed to vary freely within the two limits, the classical linear model becomes

$$y_i^* = \beta' x_i + \mu_i, \tag{12}$$

where y_i^* is the latent or sometimes unobserved variable. Denoting y_i as the observed variable, we have

$$\begin{aligned} y_i &= L_{1i} \text{ if } y_i^* \leq L_{1i}, \\ &= y_i^* \text{ if } L_{1i} < y_i^* < L_{2i}, \\ &= L_{2i} \text{ if } y_i^* \geq L_{2i}, \end{aligned} \tag{13}$$

where L_{1i} and L_{2i} are lower and upper limits, respectively, of the dependent variable for observation i. This model's likelihood function is given by

(14) $$L(\beta,\sigma|y_i, x_i, L_{1i}, L_{2i}) = \underset{y_i=L_{1i}}{\pi} \Phi\left[\frac{L_{1i}-\beta' x_i}{\sigma}\right] \underset{y_i=y_i^*}{\pi} \frac{1}{\sigma}\phi\left[\frac{y_i-\beta' x_i}{\sigma}\right] \cdot \underset{y_i=L_{2i}}{\pi}\left[1-\Phi\left[\frac{L_{2i}-\beta' x_i}{\sigma}\right]\right],$$

where ϕ and Φ are the density function and distribution function of the standard normal, respectively. This likelihood function accounts for all three possibilities given in (13). A modification of the Davidson, Fletcher, and Powell algorithm is used to optimize the likelihood function, as suggested by Gruvaeus and Joreskog. The covariance matrix is computed from analytic first derivatives of the likelihood function.

The potential for heteroscedasticity in futures price changes is well known (Hall, Brorsen, and Irwin). Hence, tests for heteroscedasticity are performed for all estimations. ML estimates of the following model, as specified by Rutemiller and Bowers and outlined in Maddala are obtained:

(15) $$\sigma_i^2 = (\tau + \delta Z_i)^2,$$

where σ^2 denotes a vector of squared error terms from the tobit models, τ denotes a constant, δ denotes a vector of parameters, and Z includes all independent variables. Likelihood-ratio tests of the restriction $\delta = 0$ are performed.

Results

To test the hypothesis that anticipated information of USDA *Hogs and Pigs Reports* has no effect on price changes after they are released, the following model is estimated for each time horizon:

(16) $$\text{Ln}(FP_t^1) - \text{Ln}(FP_t^0) = \beta_0 + \beta_1 (BRD_t^u) + \beta_2 (MKT_t^u) + \beta_3 (BRD_t^e) + \beta_4 (MKT_t^e) + \mu_t,$$

where FP denotes closing live hog futures price, a superscript 0 denotes the day of the report release, a superscript 1 denotes one trading day after the report release, and all other terms are as defined earlier. Unanticipated components are computed as the difference between actual and expected percent changes in inventories from the year-ago level. Price changes are computed as differences in natural logs so that they will represent fractional changes. The lower and upper limits for this tobit model are given by

(17) $$LL_t = \text{Ln}(FP_t^0 - LPC) - \text{Ln}(FP_t^0), \text{ and}$$

(18) $$UL_t = \text{Ln}(FP_t^0 + LPC) - \text{Ln}(FP_t^0),$$

where LL and UL denote lower limit and upper limit, respectively, and LPC denotes limit price change. For model (16), this is \$1.50 because we are dealing with one-day price changes. To test the efficient markets hypothesis, a likelihood-ratio test of the linear restriction, $H_0: \beta_3 = \beta_4 = 0$, is performed and t-statistics and standard errors of the estimated coefficients are observed.

Coefficient estimates of equation (16) are shown in table 5. No evidence of heteroscedasticity is found for any of the estimated equations. Likelihood-ratio tests and t-tests indicate that estimates of β_3 and β_4 coefficients of the

expected components are not significantly different from zero. Therefore, anticipated information has no significant effect on live hog futures price changes after the release of the USDA *Hogs and Pigs Reports*. This result indicates that anticipated information is incorporated into price before the release of the reports, supporting the efficient market hypothesis. At this point, the first test of market efficiency has been passed, and c in (1) becomes zero, causing that term to be deleted from the model.

To estimate the impact of unanticipated information on one-day futures price changes, β_3 and β_4 are dropped from (16) and the following model is estimated:

$$(19)\quad \mathrm{Ln}(FP_t^1) - \mathrm{Ln}(FP_t^0) = \beta_0 + \beta_1(BRD_t^u) + \beta_2(MKT_t^u) + \mu_t$$

for all time-horizons where LPC from (17) and (18) is also \$1.50. Standard errors and t-statistics of the estimated coefficients are examined to determine their significance. A likelihood-ratio test of the linear restriction, $H_0: \beta_1 = \beta_2 = 0$, is performed to determine the joint significance of unanticipated information with regard to breeding and market hog inventory changes.

Coefficient estimates of equation (19) are presented in the first three columns of table 6. Again, evidence of a serious heteroscedasticity problem is not found. As expected, all signs of the estimated coefficients β_1 and β_2 are negative. Of the t-statistics for unanticipated market herd changes, only that of time-horizon 1 is significant at the 5% level. This supports the hypothesis that those changes have the greatest impact on nearby futures contracts. The t-statistics of unanticipated breeding herd changes are significant at the 5% level for time horizons 1 and 2 and at the 1% level for time horizons 3 through 5. Of the coefficient estimates for unanticipated breeding herd changes, that of time horizon 1 is least in absolute magnitude (0.562). The magnitude increases substantially at time horizon 2 (1.241). The absolute magnitudes of the unanticipated breeding herd coefficients are greatest for the models reflecting a time to expiration of the contracts approximately equal to a hog production cycle (1.577 and 1.489 for time horizons 3 and 4, respectively). Beyond a hog production cycle (time horizon 5), the absolute value of the coefficient estimate drops to 0.796.

The likelihood-ratio tests, shown in the first column of table 7, indicate that β_1 and β_2 for equation (19) are jointly significantly different from zero at the 1% level for all time horizons.

Table 7. Likelihood Ratio Tests of the Response of Live Hog Futures Prices to Unanticipated Information

Time Horizon	$H_0:\beta_1, \beta_2$ (Day 1) = 0 Chi-Square(2)	$H_0:\beta_1, \beta_2$(Day 2) = β_1, β_2(Day 1) Chi-Square(2)	$H_0:\beta_1, \beta_2$(Day 3) = β_1, β_2(Day 2) Chi-Square(2)	$H_0:\beta_1, \beta_2$(Day 4) = β_1, β_2(Day 3) Chi-Square(2)
1	13.783**[a]	2.334	4.979	1.984
2	11.414**	.323	2.841	.475
3	14.161**	5.261	4.924	4.263
4	15.889**	7.364*	6.623*	1.213
5	11.961**	.335	3.912	.480

Note: For the day-one models, likelihood ratio tests are performed to determine if β_1 and β_2 are jointly different from zero at significant levels. For the cumulative two-, three-, and four-day models, likelihood ratio tests are performed to determine if β_1 and β_2 are jointly different from estimated parameter values from one-day and cumulative two- and three-day models, respectively.

[a] One and two asterisks represents significance at the 5% and 1% levels, respectively.

This result indicates that unanticipated information significantly influences futures prices along the entire spectrum of time. In sum, the results from one-day price change models support the hypothesis that live hog futures prices react quickly and efficiently to new information.

To further test the efficient markets hypothesis, it is necessary to determine if predictable price patterns exist for several days beyond one day after the report releases, given the unanticipated information. Ideally, it would be desirable to test for one-day price changes beyond the first day after release of reports. This could be accomplished by changing the left-hand side of (19) to $\text{Ln}(FP_t^2) - \text{Ln}(FP_t^1)$, and $\text{Ln}(FP_t^3) - \text{Ln}(FP_t^2)$, and so forth. However, as mentioned earlier, about one-half of all closing prices one day after report releases are limit moves, as are several closing prices two days following reports. Therefore, the procedure mentioned above would lead to biased results and is not performed. As an alternative, the following models for all time horizons are estimated:

$$(20)\quad \text{Ln}(FP_t^2) - \text{Ln}(FP_t^0) = \beta_0 + \beta_1(BRD_t^u) + \beta_2(MKT_t^u) + \mu_t,$$

$$(21)\quad \text{Ln}(FP_t^3) - \text{Ln}(FP_t^0) = \beta_0 + \beta_1(BRD_t^u) + \beta_2(MKT_t^u) + \mu_t, \text{ and}$$

$$(22)\quad \text{Ln}(FP_t^4) - \text{Ln}(FP_t^0) = \beta_0 + \beta_1(BRD_t^u) + \beta_2(MKT_t^u) + \mu_t,$$

where superscripts 2, 3, and 4 represent trading days two, three, and four after the report releases. *LPC* from (17) and (18) are $3.00, $4.50, and $6.00 for (20), (21), and (22), respectively. This alternative is followed because the dependent variables in (20) through (22) represent cumulative price changes. For example, the dependent variable in (20) represents the change in price from the close of trade on the day of the report release to the closing price two trading days later. Because prices are permitted to move by $1.50 per day, the effective cumulative two-day price limit is $3.00 in this case. The effective cumulative three-day and four-day price limits are therefore $4.50 and $6.00, respectively. The independent variables in (19) through (22) are identical.

Parameter estimates of (20) through (22) appear in table 6 under the columns for cumulative two-day, three-day, and four-day price changes. A heteroscedastic error structure is not evident for any of the estimated equations. Most of the coefficient estimates for unanticipated changes in inventories are significant for the cumulative two-, three-, and four-day price change models, as is the case for one-day price changes. However, this does not imply that prices continue to adjust after day one. A significant cumulative price change may be the result of a large and significant price change on a single day and small and insignificant price changes on the other days in the summation. To determine if prices continue to adjust after the first day following the report, coefficient estimates between days must be compared. A significant change in β_1 and/or β_2 between days for any given time horizon may indicate that information is reinterpreted in a systematic fashion.

As a formal test of the hypothesis that price patterns cannot be predicted on days beyond the first day following release of the *Hogs and Pigs Reports*, likelihood-ratio tests are performed where β_1 and β_2 in (20), (21), and (22) are restricted to their estimated values in (19), (20), and (21), respectively. The test results, pre-

sented in the last three columns of table 7, offer further evidence in support of the efficient markets hypothesis. Test statistics were insignificant beyond day one for four of the five time horizons. Predictable price patterns are indicated only for time horizon 4 contracts. As shown by the test statistics, prices at this time horizon continue to adjust through the third day following report releases.

The specific pattern of price movements for time horizon 4 contracts is suggested by the changing magnitude of the estimated coefficients for this horizon (row four, table 6). Because β_1 equals -1.489 for day one, -0.948 for day two, and -0.801 for day three, an overreaction price pattern is suggested with respect to unanticipated changes in breeding inventories. Because β_2 is equal to -0.436 for day one and increases to -0.713 for day three, an underreaction price pattern is indicated for unanticipated changes in market inventories. The relatively large change in the magnitude of coefficients for unanticipated breeding inventory changes suggests that overreaction is the dominant price pattern for time horizon 4 contracts. Finally, the results do not necessarily imply that a profitable trading strategy could be developed to exploit the apparent price patterns. This is because of the existence of price limits and the high execution costs of trading in deferred futures contracts (Thompson and Waller).

Concluding Comments

Live hog futures prices often react sharply after the release of USDA *Hogs and Pigs Reports*. Strong concerns about how efficiently live hog futures prices react to those reports have been raised by livestock producer groups. Under the efficient markets hypothesis, live hog futures price changes after the release of *Hogs and Pigs Reports* should reflect only unanticipated changes in hog inventories, and no predictable price patterns should be found.

Using market survey data as a proxy for expected changes in breeding and market hog inventories contained in quarterly USDA *Hogs and Pigs Reports*, unanticipated changes in those figures are constructed. Therefore, expected and unanticipated changes are clearly differentiated allowing for a direct test of the efficient markets hypothesis in the live hog futures market. After showing that the survey data have desirable properties of unbiasedness, efficiency, and superior forecast performance, a direct test of the efficient markets hypothesis is performed. Maximum likelihood estimation of two-limit tobit models is used to account for institutional price limits.

The results offer strong support for the efficient markets hypothesis. First, it is found that expected changes in hogs and pigs inventories are incorporated into live hog futures prices before the release of the reports, and, hence, the expected changes have no effect on price changes after the release of the reports. Second, live hog futures prices across the spectrum of time react significantly and in the expected direction to unanticipated information. It is found that nearby contract prices are most responsive to unanticipated changes in market hog inventories, while the contracts expiring at a time horizon approximating one hog production cycle are most responsive to unanticipated breeding hog inventory changes. Third, predictable price patterns beyond the first day following the release of *Hogs and Pigs Reports* are not evident for four of the five contract time horizons examined in the study. Prices for one of the deferred contract time horizons adjust through the third day following report releases. However, this does not imply that a profitable trading strategy can be constructed to exploit the apparent price pattern. The existence of price limits and high execution costs of trading in deferred live hog futures contracts are likely to preclude such a possibility.

A Simulation Model of the U.S. Export Enhancement Program for Wheat

Ann Hillberg Seitzinger and Philip L. Paarlberg

Nash bargaining game models representing negotiations of Export Enhancement Program (EEP) sales are combined with a quarterly spatial price equilibrium model representing non-EEP world wheat trade to simulate the EEP's impact in late 1985 and early 1986. The benefits of the EEP in terms of increased U.S. export revenues adjusted for subsidy costs are estimated to be less than one percent of total U.S. revenues. For the first quarter of 1986, model simulations also show a lowering of the CCC loan rate to have a much greater potential for increasing U.S. wheat exports than the EEP as operated.

Key words: export enhancement program bonus value, Nash bargaining game.

The United States introduced the Export Enhancement Program (EEP) in May 1985 to help alleviate the agricultural sector's financial stress. Payment-in-kind of export subsidies from government-owned stocks were authorized for select, or "targeted," import markets. Increased U.S. export sales were to be achieved through the displacement of subsidized European Community (EC) exports.

As a form of price discrimination among import markets, targeted export subsidies potentially can benefit the subsidizing exporter. Small export subsidies targeted toward markets with relatively more price-responsive behavior can raise export revenues or social welfare as conventionally defined. These gains are achieved without recourse to domestic policies, such as production controls (Abbott, Paarlberg, and Sharples). Further, Houck has demonstrated that in-kind subsidies may offer the exporter a positive terms-of-trade effect not available under a cash subsidy.

The EEP offers several potential benefits to the United States. Commodity groups in the United States hail the program as a success, while competing exporters complain that it has disrupted world markets. This article evaluates the impacts of the Export Enhancement Program on world wheat markets. It focuses on the program's effect on the export earnings of the United States and of its competitors. An additional scenario compares the use of the EEP to expand U.S. exports with the effect of a reduction in the Commodity Credit Corporation (CCC) loan rate. To determine these impacts, Nash bargaining models are solved iteratively with a spatial price equilibrium model of world wheat trade.

Program Operation

Knowledge of how the EEP works is critical to understanding the importance of the bargaining models to the EEP model's solution. Under the EEP, the Commodity Credit Corporation is to target countries for subsidized sales of U.S. commodities based on the following criteria:

1. additionality—sales must increase U.S. agricultural exports above what would have occurred in the absence of a program;
2. targeting—sales will be targeted on specific market opportunities, especially those that challenge competitors which subsidize their exports;
3. cost effectiveness—sales should result in a net plus to the overall economy;
4. budget neutrality—sales should not increase budget outlays beyond what would have occurred in the

absence of the program. (*Federal Register*, pp. 23750–51.)

The U.S. Department of Agriculture (USDA) may either determine its own subsidy level as done in past U.S. export subsidy programs or allow the bonus level to result from a bidding process. In the latter and more prevalent case, CCC first issues an EEP invitation to the targeted importing country specifying the maximum quantity of commodity to be exported under the invitation. Qualified firms may then negotiate conditional sales with the targeted country (FAS).

In turn, the conditional sales contracts are submitted to the Commodity Credit Corporation along with the firms' bids for EEP bonuses. A bid takes the form of a dollars and cents per unit bonus, as estimated by the firm, required to make U.S. wheat competitive with wheat from other exporting countries. The CCC accepts or rejects the EEP bonus bids on a daily basis, taking into consideration the following factors: prevailing market prices of various exporters' wheat in the targeted country, freight rates, and purchasing practices peculiar to the targeted country. A firm holding a successful bid exports the wheat to the targeted country and requests that a bonus certificate be issued by CCC. The certificate value is calculated as the per unit bonus value multiplied by the quantity of wheat shipped to the targeted country. Commodities valued at the market prices are then selected from government stocks by the individual redeeming the bonus certificate. Firms with rejected bids may revise and resubmit their bids.

As an example consider the following EEP sale to Algeria. On 4 June 1985, USDA announced the availability of EEP bonuses for up to one million metric tons of non-durum wheat destined for Algeria. Negotiations between Algeria, exporting firms, and the CCC resulted in EEP sales of 135,000 metric tons of soft red winter wheat and 170,000 metric tons of hard red winter wheat on 15 October 1985. Five exporters had submitted a total of thirty-six bids to the CCC on the previous day, of which fifteen bids from four exporters were accepted. An average bonus of $40.56 per ton was paid on the soft red winter wheat, with Algeria paying a sales price of $103.00 per ton. For the hard red winter wheat selling at $111.00 per ton, an average bonus of $42.93 per ton was paid. Thus, bonus certificates totaling approximately $12.8 million were issued in relation to these EEP sales. When redeemed for CCC wheat stocks with a prevailing U.S. market price of $115.74 per ton, 110,363 metric tons of wheat would be released from storage.[1]

The Model

Because the export subsidy under the EEP is determined by a bidding process which is influenced by and influences world market conditions, cooperative game theory is employed in constructing a simulation model. Game theory models the interaction of two or more participants, or players, with conflicts of interest. In cooperative games, the returns, or payoffs, to the players are increased by the coordination of the players' strategies. Players are able to communicate without distortions, and binding agreements are possible in the course of preplay negotiations.

Application of cooperative game theory to EEP requires definition of the players expected payoffs from cooperation and their threat strategies, or what they obtain in the absence of cooperation. In the bargaining models, a single firm is chosen to handle all EEP wheat exports. It is the only eligible receiver of EEP bonus payments in-kind. This simplifying assumption reflects the complexity and multiplicity of solutions which recognition of multiple individual competing grain-exporting firms, multinational and domestic, would introduce into an EEP bargaining model and the lack of firm-specific data required to incorporate the firms individually in the model.

This assumption limits the analysis to two extreme characterizations of industry behavior: monopolist and price taker. The assumption of monopoly allows the firm to obtain positive profits on EEP sales in a two-stage bargaining game. In one stage the monopolist and the targeted country bargain over the EEP sales price. In the second stage the monopolist and the CCC bargain over the EEP bonus. Because the monopoly results of the simulations are qualitatively similar to the competitive firm case, only the latter results are discussed in detail. The reader

[1] Bonus certificates issued before 2 Sep. 1986 specify the type of commodity available to the certificate holder. For example, bonuses paid on EEP sales of wheat before that date were paid only in wheat. Since that time generic certificates have been issued. These generic certificates may be exchanged for any commodity available in CCC stocks or may be sold to be used by producers as payment for outstanding CCC loans. Because the empirical model developed here is for the early fall of 1985 and the winter of 1986, the quantity equivalent of the EEP bonus is found by dividing the total bonus value by the market price for wheat.

interested in the outcomes under the assumption of monopolistic firm behavior is referred to Hillberg.

For the price-taking firm, EEP negotiations are characterized as a bargaining game between the Commodity Credit Corporation and the targeted country subject to the firm's zero profit condition:

$$(1) \qquad P_{ush} + B_h - P_{usus} - T_{ush} = 0,$$

where P_{ush} is EEP sales price of U.S. wheat in targeted country h, B_h is bonus per unit on EEP sales to targeted country h, P_{usus} is commercial price of U.S. wheat in the U.S., and T_{ush} is per unit transportation costs on U.S. wheat to targeted country h.

Expected payoffs to CCC are complicated by the number of objectives pursued by that agency and their conflicting nature. A weighted CCC objective function is introduced in order to capture the individual EEP goals and their relative importance. The individual components of this objective function, based on interviews with government officials responsible for operation of the program, are assumed to be the value of EC sales lost because of an EEP agreement, the value of the EEP sale, and CCC costs on EEP payment in-kind bonuses. Combining these components, the CCC weighted objective function is

$$(2) \qquad G_h = w_{ec}[P_{ech}X_{ech}] + w_x[P_{ush}X_{ush}] - w_c[(B_hX_{ush}/P_{usus})*OP],$$

where G_h is CCC benefits from EEP sales to targeted country h; w_{ec}, weight placed by CCC on displaced EC wheat sales value; P_{ech}, price of EC wheat in targeted country h in the absence of EEP; X_{ech}, exports of EC wheat to targeted country h in the absence of EEP; w_x, weight placed by CCC on EEP export value; P_{ush} EEP sales price of U.S. wheat in targeted country h; X_{ush}, sales quantity supplied to targeted country h upon which per unit EEP bonus is paid; w_c, weight placed by CCC on changes in storage costs; B_h, bonus per unit on EEP sales to targeted country h; P_{usus}, commercial price of U.S. wheat in the United States, and OP is per unit value of wheat in CCC storage.

Presence of displaced European Community sales value as the first term, $P_{ech}X_{ech}$, in the objective function shown above reflects the assumption that the EC is the sole target of U.S. allegations of unfair trade practices in operation of the Export Enhancement Program. This view is reflected in Secretary Block's announcement of the program (Block). The second term, $P_{ush}X_{ush}$, implies that any sales revenue achieved under an EEP transaction in the targeted country is considered to offer the U.S. export additionality as defined in the program guidelines above.

The third term, $((B_hX_{ush})/P_{usus})*OP$, is the budgetary cost to CCC of the EEP.[2] Wheat in CCC inventories has a value as given by its role as a government asset purchased under agricultural price support programs. But storage costs are also incurred by CCC if grain is held in government storage rather than released into less restricted channels of supply in the form of an EEP bonus. Therefore, the value of government stocks, OP, is calculated as the present value of any future selling price of the grain, which here is considered to be the CCC loan rate, less the present value of storage costs incurred until the stocks may by sold by the government. The total cost of the EEP then is the quantity equivalent of the bonus multiplied by the value of CCC stocks which, assuming a five-year storage period caused by record stock levels, was calculated to be slightly less than one-half the prevailing market price during the period simulated.

The threat payoff to the CCC of not participating in an EEP sale with a particular target is zero, or, $G_h^* = 0$. This assumes that the only damage the two players can inflict on each other is to refuse to trade.

The targeted country is assumed to weigh expenditures for purchase of wheat under EEP against importing from commercial sources. In order to capture these purchases in commercial and EEP markets, a technique employed by Roth (1986) is adopted. Roth models consumer demand in a developing country by permitting "commodity purchases in two structurally different markets—a private market, where prices and quantities are unrestricted, and the official market, where prices are fixed and quantity demanded is constrained by market rations" (Roth 1986, p. 251). In the EEP model, parallels are drawn between Roth's private market and commercial purchases of wheat from domestic and foreign sources and between Roth's official market and the market for EEP sales. Using a Stone-Geary utility function, the targeted coun-

[2] Since the inception of the Export Enhancement Program, the program guidelines have been legislatively amended to mandate program expenditure levels. Prior to this legislation, USDA exercised discretion over the lower bound on EEP spending. The Food Security Act of 1985 and the Food Security Improvements Act of 1986 authorized minimum expenditures for EEP bonus commodities of \$1.0 billion for the period October 1985 through September 1988. In extending the EEP, the Ominbus Trade Act of 1988 set funding at \$2.5 billion for October 1985 to September 1990.

try assigns utility to its consumption of goods purchased in both markets, and it wishes to maximize this utility.[3] The targeted country's problem is stated as

$$(3)\quad \text{Maximize } U_h = \sum_k B_{kh} \log (C_{kh} - Z_{kh}) + B_{wh} \log (C_{wh} - Z_{wh}),$$

subject to

$$D_{wh} + X_{ush} \geq C_{wh}$$

$$\sum_k P_{kh}C_{kh} + P_{wh}D_{wh} + P_{ush}X_{ush} \leq Y,$$

where U_h is the utility of consumption in targeted country h;

B_{kh}, marginal budget share of good k consumption in targeted country h;

C_{kh}, consumption of good k in targeted country h;

Z_{kh}, subsistence consumption of good k in targeted country h;

B_{wh}, marginal budget share of wheat consumption in targeted country h;

C_{wh}, total wheat consumption by targeted country h;

Z_{wh}, subsistence consumption of wheat in targeted country h;

D_{wh}, commercial wheat consumption by targeted country h from both domestic and foreign sources;

X_{ush}, sales quantity supplied to targeted country h upon which per unit EEP bonus is paid;

P_{kh}, domestic price of good k in targeted country h;

P_{wh}, price of commercial wheat in targeted country h from both domestic and foreign sources;

P_{ush}, EEP sales price of U.S. wheat in targeted country h; and

Y is total consumption expenditures by targeted country h.

The constraints of the problem arise from the purchase of wheat in a commercial market covering both domestically produced and imported wheat and in a subsidized market provided under the Export Enhancement Program. The first restriction requires the level of wheat purchased in the two markets to equal or exceed the total quantity of wheat consumed by the targeted country. In the second constraint, expenditures on all goods, whether commercial or subsidized, may not exceed available targeted country income. A third constraint requiring the total quantity of EEP sales to be less than the maximum amount of wheat made available to the targeted country under EEP announcements was not included in the problem formulation for the following reason. Judged on a quarterly basis the maximum levels of allowable EEP sales determined by CCC are usually set at levels which are far higher than the potential for consumption in an individual target prohibited from re-exporting any surplus to other countries.

Because wheat is assumed to be a homogenous commodity in this formulation, if the EEP sales price is lower than the commercial import price of wheat, up to the maximum quantity of EEP wheat available to the targeted country is purchased before the country turns to commercial imports. In an Armington model with supplier-based product differentiation, the EEP would easily replace U.S. commercial wheat; but it would have more difficulty replacing rival suppliers' wheat. Thus, the formulation presented here should be viewed as revealing the maximum displacement of other countries' wheat trade by EEP.

Given the above formulation, an expenditure function is derived. Taking into account consumption of domestic production and the possibility of food aid commitments and long-term agreements continuing some quantity of restricted imports, $\bar{D}_{wh}$, the targeted country's expenditure function for subsidized EEP purchases and constrained commercial expenditures is

$$(4)\quad E_h = B_{wh}\,[Y - \sum_k P_{kh}Z_{kh} - P_{ush}Z_{wh} + \bar{D}_{wh}\,(P_{ush} - P_{wh})] + P_{ush}Z_{wh} - P_{ush}\bar{D}_{wh} + P_{wh}\bar{D}_{wh}.$$

The components of expenditure are the share of discretionary income claimed by imports of wheat plus the subsistence level of wheat imports by the targeted country as represented by the first and second terms. The final two terms represent the additional expenditures incurred by the targeted country in choosing to continue some level of imports from the higher priced non-EEP markets.

The threat strategy available to the targeted country is to purchase all wheat in commercial channels. This yields the familiar LES expenditure function, denoted E_h^*, as the targeted

[3] This utility function has two advantages for this problem. First, it allows a separation between the EEP market and the commercial market. Second, it yields a linear expenditure function which eases solution of the Nash bargaining problem.

country's threat payoff function.

The expected payoff functions and threat strategies for the CCC and the targeted country are employed to define the set of feasible EEP agreements. The bargaining problem is to find a unique outcome within the set which will define whether an EEP sale occurs and at what subsidy level. Nash provides a mechanism for determining this unique point which requires the distribution of payoffs under agreement to conform to certain prespecified criteria or axioms. The Nash solution assumes that cardinal utility-maximizing players of equal bargaining skill have initial endowments and preferences which define an area of mutual gain from bargaining. Any extension or reduction of this area can take place only if the unique solution is included in the revised area.

For the EEP bargaining game, the Nash bargaining problem is stated as

$$(5) \quad \underset{B_h}{\text{MAXIMIZE}}\ (G_h - G_h^*)*(E_h^* - E_h),$$

where G_h, E_h are expected payoffs to the CCC and the targeted country, respectively, under cooperation; and G_h^*, E_h^*, "threat strategy," what the CCC and the targeted country, respectively, obtain in the absence of cooperation. As can be seen, the function forms a mapping of parabolas. Maximizing this function determines a unique point on the boundary of the feasible set of outcomes where a parabola is tangent to the boundary. Applications of this model in empirical wage negotiations research suggest that the Nash solution is able to explain the behavior of bargaining entities such as firms and labor unions and not just the behavior of individuals as studied in experimental work (Bognanno and Dworkin, de Menil, Roth 1979, Siegel and Fouraker).

Two components then determine the EEP bonus when the Nash solution is applied. The first component is one-half the bonus which would make the CCC indifferent between returns under cooperation and returns under the threat strategy. Similarly, the second component is one-half the bonus which would make the targeted country indifferent between purchasing under an EEP agreement and purchasing solely in the commercial markets.

A spatial price equilibrium model is solved iteratively with the Nash bargaining models for each target to allow the simultaneous determination of EEP and non-EEP trade flows and prices. Quarterly trade elasticities are combined with base price and quantity data to construct linear non-EEP excess demand and excess supply schedules for all the regions included in the model except the United States.

Specification of U.S. excess supply involves subtracting five components of demand for U.S. wheat from a fixed quarterly supply. Individual schedules determine food and feed demand, farmer-owned reserve stockholding, CCC stockholding, and private stockholding. The fifth demand component, that of EEP, is determined by the bargaining models. The purpose of this more detailed representation of the U.S. wheat market is to include a mechanism which releases EEP bonus commodities from CCC storage where stocks are subject to legislated release rules into less regulated channels of supply. In this manner, the payment of EEP bonuses in-kind from CCC storage, rather than in cash, is recognized. Additionally, the interaction of the EEP with domestic policy provisions such as CCC loan rates is incorporated in the model. In the empirical results which follow, the level of U.S. policy instruments, especially the loan rate, is critical to the effects of the program.

Base Solutions

Determination of a base solution for the EEP model requires one further set of model parameters. Because the priorities placed by the CCC on the targeting, additionality, and cost components of the payoff function are not known with certainty, EEP model simulations are used to determine sets of weights for the CCC payoff functions. Three different rules were applied in the search for these weights. First, the weight placed on the value of the EEP sale was set at zero, leaving the CCC with the combined objectives of displacing EC sales value in the targeted country and controlling program costs. Second, the value of displaced EC sales received a zero weight. In this case, the CCC's interests turn toward increasing the EEP sales value to the targeted country in addition to controlling program costs. Third, equal values were placed on the weight for displaced EC sales in the targeted country and on the weight for EEP sales to the targeted country.

Table 1 compares actual data with the base solution results chosen from these three simulations. The base solution weighting schemes are selected based on their ability to predict the success and the failure of EEP sales to individual targets and the similarity of the weighting

Table 1. Bargaining Game Base Solutions

schemes across targets.[4] The two quarters of program operation simulated, October to December 1985 and January to March 1986, are the first and second quarters in which EEP sales to multiple targeted countries were completed.

Two separate weighting schemes were chosen to determine the base solutions in the quarters under study. For October to December 1985, the CCC is assumed to weigh the benefits of displacing EC sales value in the targeted country against the costs of providing bonus commodities. For January to March 1986, the base solution assumes that the CCC desires to increase EEP sales value to the targeted country while controlling program costs. The passage of legislation mandating minimum annual expenditures on EEP in late December of 1985 supports the empirical results of these models that CCC program objectives shifted during the quarters under study from targeting EC markets to increasing EEP sales value wherever possible.

While the base solutions in table 1 are quite accurate in their estimates of the EEP bonus levels for the individual targets participating in model results, the EEP price tends to be underestimated in the October to December 1985 quarter and the EEP quantities are overestimated in both quarters. The low estimate of the EEP price indicates that the zero profit condition applied to the exporting firm is inappropriate for the October to December 1985 quarter. Comparison of simulation results with actual data indicates pos-

[4] Each of the simulations was unable to predict the EEP sale completed with Turkey without assigning the country lower payoffs than it would achieve in the absence of a sale. A very high trade elasticity was calculated for Turkey because its imports were small relative to its domestic production of wheat. This high elasticity caused Turkey to respond to the lower EEP price by purchasing a much greater quantity of imports such that the level of total expenditures rose. Under the assumptions of the linear expenditure system, this increase in expenditures leads to a decline in utility. For a more complete discussion of the derivation of CCC weights, see Hillberg.

itive firm profits of approximately $2.40 per ton on sales to Algeria and $3.50 per ton on sales to Morocco. These results suggest that the firms had some influence over the EEP price which is understated in the competitive model. The monopoly bargaining models for this same period overstate the exporting firm's influence. Results for the quarter January to March 1986 show that the estimates of the subsidized price are no longer uniformly lower than the actual EEP prices.

The difficulty of the model in its prediction of the quantities shipped under the EEP lies with the lag between purchase and shipments of wheat in international trade. Delivery dates cited for a subset of EEP shipments (GAO) indicate that the three-month lag between purchase and shipping employed in the model is representative on average, but instances of shipment in the same quarter as purchase or with a two-quarter lag are known. Combining the quarterly estimates reduces the magnitude of the error.

When summed over all the targeted countries participating in EEP sales, the bargaining models show a 9% overestimate and a 6% underestimate of the total value of EEP bonuses awarded for October to December 1985 and January to March 1986, respectively. The total quantity of EEP shipments made during these quarters was underestimated by the bargaining models with errors of 3% and 7%, respectively.

World Wheat Market Impacts of the EEP

The impact of the program is estimated through a comparison of the EEP base solution with simulation of the spatial price equilibrium model assuming the absence of the program. For October to December 1985, although 1.2 million metric tons are shipped under the EEP, world trade increases by only 110,000 metric tons, or less than 1% compared with model results without the EEP. During January to March 1986, increases in world trade are also held at less than 1%.

For the United States, October to December 1985 total wheat exports rose by 3% from 5.8 to 6.0 million metric tons because of the EEP. U.S. wheat exports for January to March 1986 rose by 2%, from 5.4 to 5.5 million metric tons. These results then indicate a high rate of displacement of commercial sales by subsidized sales in both quarters under study. For the targeted countries participating in successful EEP sales, the percentage increases in total imports are as follows: Algeria (+6% to +8%), Morocco (+7% to +10%), Zaire (+2%), and the Philippines (+3%).

In terms of trade flows, the model results show the United States leaving markets in developed Asia and Africa and moving into the targeted countries' markets. Displacement of the EC by the United States in North African markets is compensated by increased EC trade with the USSR and other African markets. As the EC displaces Australia in the Soviet market, Australia ships increasingly to the developed Asia market given up by the United States.

The U.S. price effects of the EEP for October to December 1985 are slightly positive as the border price rises from $135.31 to $135.56 per ton. Where approximately 330,000 metric tons of EEP bonus wheat are awarded during the quarter, ending CCC stocks are reduced by only 45,000 metric tons because of additional CCC loan forfeitures of 285,000 metric tons. Farmer-owned reserve stocks remain unchanged by the EEP, while free stocks decline by 120,000 metric tons. Domestic demand for food and feed wheat is lower by 3,000 metric tons. The results for January to March 1986 show a similar pattern as the U.S. border price rises from $133.72 to $133.94.

The increases in the U.S. export volume and border price lead to a rise in export revenues of 3% for October to December 1985, as shown in table 2. However, if these revenues of $817 million are adjusted for the cost of the bonus commodities to CCC, $20.2 million, the increase in U.S. export revenues due to the EEP is less than

Table 2. Estimated Export Revenues and Subsidy Costs

	No EEP	Base Solutions
	------ ($ million)	------
October to December 1985		
U.S. Total Revenues		817.2
Subsidy Costs		20.2
Adjusted Revenues	792.7	797.0
Canada	375.8	375.8
EC	506.5	499.1
Australia	674.9	670.0
Argentina	371.6	370.2
January to March 1986		
U.S. Total Revenues		740.2
Subsidy Costs		11.7
Adjusted Revenues	722.5	728.4
Canada	464.4	457.6
EC	302.4	297.1
Australia	597.0	598.9
Argentina	115.6	115.9

1%. For January to March 1986, the model also suggests a less than 1% increase in U.S. export revenues. If the costs of the additional CCC loan forfeitures are also recognized as a cost of the EEP, U.S. export revenues adjusted for program costs fall below levels achieved in the absence of the program.

According to the model results, the effect on other exporters of the EEP is also very slight. Declines of only 1% in European Community export volume are shown for both of the quarters under study. Combined with slight declines in border prices, EC export revenues fall by almost 2% in each quarter.

For Canada, Australia, and Argentina, the negative effects of the EEP on export revenue are less than 1% for October to December 1985. For January to March 1986, results also indicate very small changes in export revenue for this group of exporters. However, in contrast to the previous quarter's results, these changes in revenue, while again less than 1%, are now positive for Australia and Argentina. These contradictory results are caused by the abrupt changes in trade flows which occur in simulations using spatial price equilibrium models. The magnitude of these changes suggest very small effects of the EEP on Canada, Australia, and Argentina during the periods under study whether in a positive or negative direction.

Lowered Loan Rate Simulation

The simultaneous release of EEP bonus wheat and acquisition of loan forfeitures by the CCC raises the question of how the program might have operated if the lower loan rate legislated for the 1986 crop year were in effect during the quarter January to March 1986. In order to address this question, two further model simulations are run. First, the loan rate is lowered from \$147.00 to \$114.00 per ton, and corresponding downward adjustments to the price expectations of commercial stockholders are made. Thus, solutions with a lowered loan rate but without the EEP are obtained. The second simulation adds the EEP to the lowered loan rate environment.

With only the lowered loan rate, U.S. wheat exports increase by 2.0 million metric tons or 37% during the quarter. Approximately 1.3 million metric tons of the increase in U.S. exports come from what may be considered a one-time reduction in private stock levels because of altered price expectations. The price of wheat in the United States is \$11.23 per ton lower, falling from \$133.72 to \$122.49 per ton. Competing exporters respond to lowered market prices with a 1.0 million metric ton reduction in wheat exports.

U.S. exports rise by an additional 100,000 metric tons because of the EEP in combination with a lowered loan rate. Adjusting for an estimated one-time downward adjustment in private stocks, lowering the loan rate alone increased U.S. exports by 13%, while the EEP created an additional 2% increase in exports. The lower loan rate prevents the acquisition of additional CCC stocks in the form of loan forfeitures. Thus, the release of 184,000 metric tons in bonus commodities from CCC storage leads to an additional fall in the U.S. border price from \$122.49 to \$122.31 per ton. The net effect of these changes is to reduce U.S. export revenues adjusted for the cost of the subsidies below levels achieved in the absence of EEP. Table 3 shows this decline of U.S. export revenues due to the EEP from \$908 million to \$906 million.

For all the other exporters—the EC, Canada, Australia, and Argentina—lower export quantities are combined with declining border prices under the lowered loan rate and the EEP. The lowered loan rate alone leads to a 16% decline in the level of other exporters' revenues from wheat exports. The EEP further reduces competing exporters' revenues, but by less than 1%.

Conclusions

This study employed Nash bargaining models to analyze the impact of the Export Enhancement Program. The results suggest that this model is able to explain the EEP prices, bonuses, and quantities for the period October 1985 to March 1986, although the estimates of quantity are subject to greater error. Examination of the EEP

Table 3. Comparison of an EEP Under a Lowered Loan Rate and the Absence of EEP with a Lowered Loan Rate: Estimated Export Revenues

	January to March 1986		
	No EEP	EEP	Change
	---- (\$ million) ----		
United States	908.1	906.9	
Canada	378.5	377.1	
EC	234.1	233.0	
Australia	526.6	525.1	
Argentina	104.4	104.2	

program suggests a change in CCC objectives between October to December 1985 and January to March 1986. The earlier quarter shows a stronger desire to complete sales in markets supplied by the European Community, while the later quarter indicates a greater priority placed on expanding EEP sales to all targets.

The benefits of the Export Enhancement Program to the United States during the quarters studied were estimated to be small and relied on the simultaneous release of EEP bonus wheat from CCC storage and acquisition of loan forfeitures by the CCC. Measured in terms of export revenues adjusted for the costs of the EEP subsidies, these benefits of a less than 1% increase in U.S. revenues disappear if the costs of the additional CCC stocks acquisitions are incorporated in the model as a cost of EEP operation. In the presence of a lower loan rate, the lack of additional loan forfeiture acquisitions by the CCC leads to U.S. export revenues lower than they are estimated to be in the absence of the program.

Given the program as operated in this period, these scenarios suggest that the fall in the CCC loan rate caused a far larger increase in U.S. wheat exports than did the EEP. Adjusting for an estimated one-time downward adjustment in private stocks, lowering the loan rate alone increased U.S. exports by 13% while the EEP created an added 2% increase in exports. Other exporters must adjust to marked changes in trade flow patterns. However, the impact of the EEP on their export levels and border prices during these quarters is very slight, although generally in a negative direction. The impact of the lowered loan rate on these countries is far more significant.

Valuing Trade-Offs between Net Returns and Stewardship Practices: The Case of Soil Conservation in Saskatchewan

G. C. Van Kooten, Ward P. Weisensel, and Duangdao Chinthammit

In this paper, a trade-off function between net returns and soil quality is developed for farmers in southwestern Saskatchewan using a Markov decision model. The results show that farmers who are concerned with soil levels or stewardship employ chem-fallow more often at lower soil moisture levels and also tend to crop more intensively to conserve soil. The major conclusion is that concern for soil quality, as documented by some researchers, does have practical significance in changing agronomic practices; but, when soil is relatively deep, it takes a fairly substantial concern about soil quality before it is possible to distinguish clearly the agricultural practices of farmers who are truly concerned with stewardship from those who are not.

Key words: dynamic programming, economic trade-off, soil conservation.

Research indicates that agricultural producers do not behave solely as profit maximizers, but that they usually maximize some form of utility function (Lin, Dean, and Moore; Van Kooten, Schoney, and Hayward). As Paterson discovered, soil stewardship is a priority for many farmers and should be included in the utility function. Stewardship implies that the soil resource be used so that long-term productivity is not diminished; however, in practice, interpretation of the term "stewardship" varies among individuals. The purpose of this study is to investigate the relevance of stewardship to farming practices and, in particular, to investigate the ability and willingness of individual farmers to sacrifice profits for soil quality. Therefore, soil quality is explicitly included in the farmer's utility function along with profit, and a trade-off function between soil quality and net returns is constructed in a dynamic framework.

An example of the approach used here is provided by Thampapillai and Sinden (TS) who determine trade-offs for multiple objective planning in northern New South Wales in Australia. Their model consists of a function with two objectives—a monetary objective, income maximization, and a nonmonetary objective, maintenance of environmental quality. The trade-off function was derived by changing the relative weights on these objectives. Unlike TS, who employed deterministic linear programming, we use a (dynamic) Markov decision model here to study trade-offs among objectives.

Our focus is on how optimal farm management practices are affected by various levels of concern for stewardship. We assume that agricultural producers in the brown soil zone of southwestern Saskatchewan maximize discounted utility as a function of net returns and soil quality, where soil quality is measured by soil depth. We examine flexcropping of spring wheat in conjunction with either tillage fallow or chem-fallow for moisture conservation. As opposed to a fixed crop rotation, such as the dominant two-year, wheat-fallow rotation in the study region, the flexcrop strategy relies on a measure of spring soil moisture to determine whether to plant or fallow (Burt and Allison).

The authors are an associate professor, Department of Agricultural Economics, University of British Columbia; a research associate, and a former graduate student, respectively, in the Department of Agricultural Economics, University of Saskatchewan.

They wish to thank Douglas Young and Oscar Burt for their encouragement throughout this research and two anonymous *Journal* reviewers for their helpful comments and suggestions. However, any remaining errors are the responsibility of the authors alone.

The critical soil moisture level and, hence, the cropping strategy and extent of subsequent erosion are affected by stewardship concerns.

The following sections develop a theoretical foundation for the problem and describe the empirical model. Then, stochastic dynamic programming (SDP) is used to solve the Markov decision process and find the optimal flexcrop strategy under various weights for the two objectives in the utility function. A trade-off function between the attributes is developed and time paths of soil erosion under various weightings of the soil quality objective in the utility function are investigated.

Theory: Trade-off between Net Returns and Soil Quality

It is assumed that farmers maximize the discounted value of a multi-objective utility function. The parameters of the utility function are net returns (π) and soil quality (Q), where soil quality is synonymous with minimizing soil erosion (i.e., soil conservation).[1] As a practical matter, soil quality is converted into a money measure by determining the productive value of soil depth. A model for analyzing the trade-off between soil quality and profit is illustrated in figure 1. Soil quality is plotted along the al scissa while profits are plotted along the ord nate. Because erosion is a dynamic concept, bo the profit and soil quality axes can be expresse in present value terms.

Point A defines the initial distribution of pro its and conservation, i.e., soil quality or dept prior to any decision making on the part farmers. Curve GF is the transformation fronti or trade-off function. This envelope of feasib alternatives includes all possible farming stra egies, that is, agricultural practices or uses f the land over time. Along the frontier, the ma ginal rate of transformation (MRT) measures tl sacrifice of discounted profit for a unit increa in present value of soil quality. The MRT is d fined as

$$MRT = -d\pi/dQ = (\delta g/\delta Q)/(\delta g/\delta \pi),$$

where $g(\pi, Q)$ is a convex function, the tran formation locus.

An indifference map is superimposed on tl transformation curve in figure 1. The farmer discounted utility function is expressed by is present value of utility (indifference) curves which the marginal rate of substitution (MR between soil quality and profits is defined as

$$MRS = -d\pi/dQ = (\delta U/\delta Q)/(\delta U/\delta \pi).$$

Farmers attain their highest indifference conto at point E, where $MRT = MRS$ in the feasib set. The line (MM') passing through E and ta gent to both the transformation locus ar

[1] Soil conservation is a shift of extraction rates toward the future, while soil depletion or erosion is a shift of use rates toward the present (Ciriacy-Wantrup).

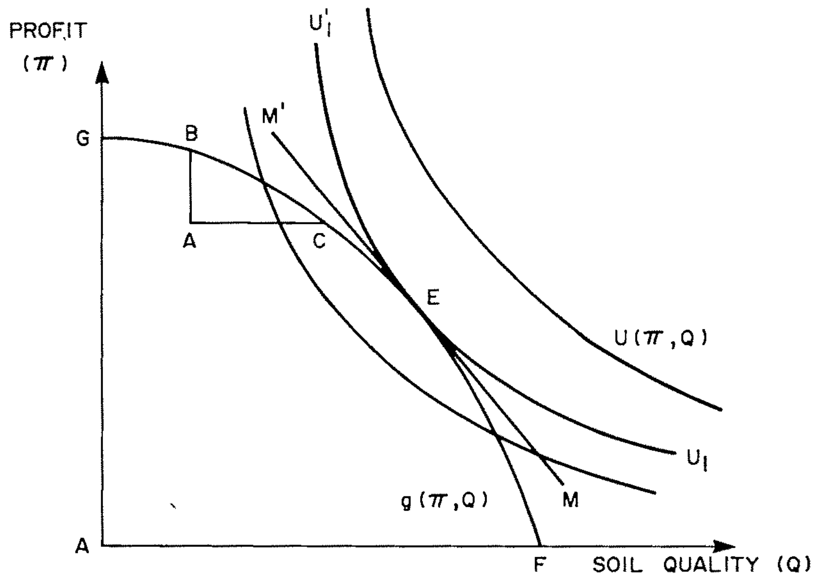

Figure 1. Trade-off function for profit and soil quality

U_1U_1' is important because the negative slope of MM' indicates the relative marginal values of π and Q held by the decision maker. We refer to the marginal trade-off of Q for the other objective as a weight. Therefore, the slope of U_1U_1' at point E is the negative of the ratio of the soil quality weight in the utility function to the weight for profits. If the latter weight is one and the soil quality weight is λ, the slope of MM' is then $-\lambda/1 = -\lambda$. In equilibrium, therefore, $MRT = MRS = \lambda$. By choosing different values of λ in a dynamic decision model, it is possible to find GF.

Given the dynamic nature of soil erosion and cropping systems, a dynamic optimization model is used to determine the trade-off function between net returns and soil depth. The objective function is

$$(1) \qquad \sum_{t=0}^{T} U_t(\pi_t, Q_t)\, \beta^t,$$

where $\beta = 1/(1 + r)$ is the discount factor, with rate of discount r, and T is the length of the planning horizon. Net returns depend upon the choices available to the decision maker. In the model, farmers can select from the following choices (d) at spring planting time: (a) plant wheat; (b) summerfallow to store soil moisture for next year's crop, using tillage operations to keep fields free of weeds; or (c) use chem-fallow to store moisture and protect the soil from eroding to the extent it does under tillage fallow. The state variables in the model are soil depth (D) and available soil moisture (M) at spring planting time (early May).

The utility function is assumed to be strongly separable in net returns and soil quality. After a monotonic transformation of the utility function, the objective function (1) can be written as

$$(2) \qquad \sum_{t=0}^{T} [(1 - \lambda)\, \pi_t + \lambda\, Q_t]\, \beta^t,$$

where $0 \leq \lambda \leq 1$ is the utility weight attached to the soil quality objective. Soil quality is a function of the state variables, moisture and soil depth; that is $Q(D_t, M_t)$.[2] The soil quality function itself remains invariant with respect to time.

The objective function (1) is maximized subject to the following state transformation equations:

$$(3) \qquad D_{t+1} = D_t - h(d_t, D_t), \text{ and}$$

$$(4) \qquad M_{t+1} = M_t + g(d_t, M_t).$$

Dynamic constraint (3) states that soil depth in the next period is equal to the current period value minus the soil extracted by farming operations (tillage fallow, chem-fallow, or crop). Transformation equation (4) states that available soil moisture next year is related to current soil moisture and the agronomic decision either to exploit moisture (crop) or enhance moisture (tillage fallow or chem-fallow).

Both the state variables—available soil moisture at planting time and soil depth—are stochastic variables. Soil moisture is stochastic because annual precipitation is unpredictable. However, the distribution of moisture available at the beginning of a crop year is dependent on the decision in the preceding year. Similarly, the soil erosion experienced in a given year depends on the agronomic decision taken, with uncertainty attributed to vagaries in weather conditions. Unlike soil moisture, however, soil depth is continually declining in random fashion because soil regeneration is considered insignificant.

A particular state is defined as a pair of observations on soil moisture and soil depth. Hence, the SDP recursive equation can be written as

$$(5) \qquad V_t(i) = \max_{d(t)} E[R^d(i) + \beta \sum_{j=1}^{m} p^d(i, j)\, V_{t+1}(j)],$$

where $V_t(i)$ is the discounted value of future net returns, given the state variable is at level i at the beginning of the T-stage process,[3] $V_{t+1}(j)$ is the discounted value of future net returns over the remaining $T - 1$ years of a T-year horizon, given the state conditions are at level j and that the optimal path is followed; $p^d(i, j)$ is the probability of moving from state i to state j, given that alternative d is chosen; $R^d(i)$ is the reward in state i, given decision d; and there are a total of m states. Equation (5) is solved recursively to yield the optimal solution.

Data for the Study Region

The data used in the study come from the Innovative Acres Project administered by the Department of Soil Science at the University of

[2] This relationship is described further in the empirical section.

[3] Each of a finite number of states consists of a combination of some level of soil moisture and soil depth.

Saskatchewan. The major objectives of this project are to maximize crop productivity and sustain high soil quality through the implementation of water-efficient farming practices. For each Saskatchewan farm in the program, data have been collected from an average of twenty-four plots spread over two research fields; but, for each plot, data are only available for a period of four years. (The few years of available data, unfortunately, will affect the generality of the conclusions.) Only data from the eleven Innovative Acres farms located in the brown soil zone of Saskatchewan are used in this study.

The following variables are included in the data; (*a*) the depth of the *A* and *B* soil horizons (solum depth), (*b*) the level of available soil moisture at planting time, and (*c*) the type of crop seeded and its yield. The data include observations of both conventional and chemical fallow, and the dominant crop in the region is hard spring wheat. The average wheat yield for the farms in the study area is 1,622.87 kilograms per hectare (24.1 bushels per acre), which accords with historical yields for wheat. The ten-year (1977–86) average spring wheat yield in the region was 1,649.93 kg/ha (24.5 bu/ac). Further information regarding the data is found in Weisensel.

If no crop is grown, then yield is zero and only a cost of fallowing is incurred. The cost of the fallowing strategy depends upon whether tillage fallow or chem-fallow is employed. Cost of production data, which is based on total variable costs of production, was obtained from Schoney and is provided in table 1. The cost of chem-fallow is from the Innovative Acres data, but it is comparable to the other cost data. Adjustments were made to the cost structure as solum depth changed in order to keep production on the expansion path (see Weisensel). In addition, the costs of chem-fallow and tillage fallow are adjusted to account for lower seeding costs on fallow as opposed to stubble (table 1). However, because the model does not include decisions regarding optimal investment in machinery and equipment, it is assumed that fixed costs remain the same over the length of the planning horizon. Thus, the focus is on variable profits.

Table 1. Cost of Production Data for Brown Soil Zone of Saskatchewan

Description	Cost
	($Cdn/hectare)
Wheat on fallow	98.60
Wheat on stubble	112.73
Cost adjustment for seeding on summer-fallow vs. stubble	14.13
Tillage summer-fallow	20.85
Chem-fallow	47.42

Estimated Yield Function and the Measurement of Soil Quality

The net return (variable profit) in any given year is the price of output (P) multiplied by yield (Y) minus the cost of the activity (c). Yield is a function of the state variables solum depth (D) and available soil moisture (M) at spring planting time. Of course, yield is zero if the land is not cropped. The yield function is stationary, price is fixed, and the cost or production depends only on the decision (d), which is fixed for each activity. Thus, net returns can be written as

$$\pi_t(d_t, M_t, d_t) = P \cdot Y(D_t, M_t, d_t) - c(d_t).$$

This expression is then substituted into (2).

The yield function is assumed to take a modified Mitscherlich-Spillman functional form:

$$Y = a + b\,(1 - R_1^D)\,(1 - R_2^M),$$

where a, b, R_1, and R_2 are parameters to be estimated, D is centimeters of solum depth, and M is centimeters of available soil moisture.[4] The estimated relationship is

$$\begin{aligned}(6)\quad Y = \underset{(0.27)}{84.02} + \underset{(7.67)}{2808.1}(1 - \underset{(2.16)}{0.634}^D)\\ \cdot(1 - \underset{(28.3)}{0.926}^M),\ R^2 = 0.22,\end{aligned}$$

where the t-statistics are provided in parentheses and there are 484 observations. Equation (6) represents the expected yield function for farmers, assuming that solum depth and available soil moisture are known at planting time.

The soil quality objective is made commensurable with net returns by specifying the value of soil in monetary terms. A dollar value for soil quality is obtained by integrating the value of marginal product (VMP) curve for solum depth [obtained from (6)] between zero and the amount of solum depth in the field. The value of the marginal product of solum depth is

[4] Other functional forms were also examined, but this form gave the best results from both a statistical and agronomic viewpoint (Weisensel).

$$VMP = P\ \delta Y/\delta D = P[-b\ \ln R_1\ R_1^D\ (1 - R_2^M)].$$

Suppose q is a given solum depth. Then the value of q to the producer, say Q, is found by integration.

$$\begin{aligned} Q &= \int_0^q VMP\ dD \\ &= \int_0^q [-P\ b\ \ln R_1\ R_1^D\ (1 - R_2^M)]dD \\ &= Pb(1 - R_2^M)\ (1 - R_1^q). \end{aligned}$$

In (7), Q measures the shadow value of soil quality and is our surrogate for soil quality in the utility function.

To reflect a distaste for fallow in the current period as opposed to planting a crop, the soil quality metric in the objective function is multiplied by a factor μ determined by the ratio of expected soil loss under the particular decision taken to the soil loss expected when land is cropped. Thus, if the decision is to crop, then the adjustment factor is 1.0; it is less than 1.0 for either of the fallow decisions (table 3).

Because the objective function (2) is separable in the two objectives, profit and soil quality, it can now be written as

$$(8)\quad \sum_{t=0}^{T} \{(1 - \lambda)\ P\ [84.02 + 2808.0\ (1 - 0.634^{D_t}) \cdot (1 - 0.926^{M_t}) - c(d_t)] + \lambda\ \mu\ P\ [2808.0\ (1 - 0.634^{D_t}) \cdot (1 - 0.926^{M_t})]\}.$$

Although the dual objectives are commensurable in expression (8), this does not imply that the agricultural producer considers \$1 of net return to be identical to \$1 from soil conservation. Rather, one can think of π as realized returns and Q as unrealized or psychological returns. This explains the similarity (but not equality) of expressions (6) and (7).

State Transformation Equations: The Transition Matrix

In the SDP model, the state transformation equations (3) and (4) are represented by a probability transition matrix giving the probability $P^d(i, j)$ of moving from state i in time t to state j in time $t + 1$ given that decision d was made at time t. In order to compute the entire transition matrix, a transition matrix for each of the state variables, soil moisture and solum depth, must first be calculated.

The following procedure was employed to calculate the soil moisture transition probabilities. Spring soil moisture in the year following a spring wheat year is regressed on spring soil moisture of the preceding crop year. The data on soil moisture are described in detail by Chinthammit. Similarly, spring soil moisture in the year following fallow is regressed on spring soil moisture of the fallow year for each of tillage fallow and chemical fallow. A double logarithmic functional form was used for the three regressions. The results are as follows:

(9a) Spring wheat:
$$\ln M_t = \underset{(12.33)}{1.6017} + \underset{(4.07)}{0.2271} \ln M_{t-1},$$
$$R^2 = 0.0434,\ SEE = 0.5075, \text{ and } n = 367;$$

(9b) Regular fallow:
$$\ln M_t = \underset{(18.66)}{2.0212} + \underset{(4.95)}{0.2286} \ln M_{t-1}$$
$$R^2 = 0.1052,\ SEE = 0.3075, \text{ and } n = 210;$$

(9c) Chemical fallow:
$$\ln M_t = \underset{(10.71)}{1.9693} + \underset{(3.04)}{0.2587} \ln M_{t-1}$$
$$R^2 = 0.1371,\ SEE = 0.3301, \text{ and } n = 60.$$

Here, SEE is the standard error of the estimate, n is the number of observations, and the t-statistics are provided in parentheses.

As expected, the intercept and slope for the spring wheat equation are lower than for both the fallow equations. A Breusch-Pagan test was employed to test for heteroscedasticity in the soil moisture state equations. The null hypothesis that the error term is independently and identically distributed could not be rejected at the 95% level.

Soil moisture is divided into ten discrete intervals in the SDP model. The intervals and their midpoints are provided in table 2. The probability transition matrix has a dimension of 30 by 10 to account for the three alternatives—tillage fallow (F), chem-fallow (C), and planting spring wheat (W). The soil moisture transition matrix is constructed using the results in equations (9).

To illustrate the method used to construct the matrix, consider alternative W in the fifth state (i.e., row 15 of table 2). Substitute the soil moisture value of 11.25–the midpoint of soil moisture interval 5—in the right-hand-side of (9a). This gives an expected mean of 8.60 centimeters of moisture. Assuming soil moisture has

a log-normal distribution, with variance given by *SEE* (=0.5075), it is possible to determine the probability that soil moisture will fall into a particular interval next year given that a crop is grown this year. This process is repeated for each row; each row constitutes a probability distribution and thus must sum to 1.0. In table 2, both the rows and columns are unimodal or exhibit monotonicity, but there is some inconsistency in the last several columns of the transition table. However, this problem does not significantly affect the results because the differences in probabilities are small.

The solum depth transition matrix is constructed from the erosion estimates of table 3; the last column in table 3 gives the adjustment factors μ for a 10%–24% slope. The transition matrix is based on the assumption that the erosion estimates are normally distributed (Kiss, de Jong, and Rostad). Given the estimates and their standard deviations, distribution theory can be used to calculate each row of the matrix. For each initial state i at time t, the normal distribution was integrated over each interval j, where j is the corresponding value of the state variable in time period t + 1, using the rate of erosion associated with particular alternative d. The result is the probability of moving from state i to state j, given alternative d is chosen. Repeating this operation for all intervals j in row i will complete the first row of the transition matrix. To complete the remainder of the matrix, the distribution function must be integrated for all states i, over all intervals j, and for all alternatives d (Weisensel).

The solum depth transition matrix for a slope grade of 10%–24% is provided in table 4 with a format similar to the soil moisture matrix in table 2. The higher slope grade represents a serious risk of erosion; it is used here for illustrative purposes, although similar results hold for lower slope grades. The solum depth transition

Note: See table 2 for further explanation.

matrix, which is based on 20 centimeters (cm) of solum depth with 2-milimeter intervals, has dimensions 300 by 100 because, for every solum depth state, there are three possible alternatives. The majority of values in the matrix are zero because it is highly unlikely, even on high risk soils, that more than 2 to 3 centimeters of topsoil can be eroded in a single year. Furthermore, the model does not account for soil deposition or regeneration; thus, the probability of increasing solum depth is zero.

Every third row of the solum depth transition matrix is exactly the same except that it is shifted to the right one column. This result occurs between each row of the matrix (for the same alternative) is calculated using the same erosion estimate from table 3. Finally, solum depth cannot be eroded below zero. Because the probabilities in the bottom rows of the solum depth matrix must reflect this phenomenon, the final rows of the matrix are modified so that the probabilities in each row still add to one. This is done by calculating the probability of the 100th column as one minus the sum of the previous 99 columns for the given row. Because of the size of the solum depth transition matrix, the number of zeros in it and the similarity of the rows (except for the last several), only the first three rows and eight columns are shown in table 4.

The solum depth and moisture probabilities are assumed independent of each other. Therefore, the total transition matrix for the system is found by multiplying each entry for a given solum depth state by the row associated with a particular soil moisture state. The new states created in this way consist of a paired observation on solum depth and available spring soil moisture.

Optimal Flexcrop Strategies

Because soil is continually being eroded, value-iteration over a period of thirty years is used to solve the SDP problem. A price of $Cdn.128.52 per tonne ($3.50/bu) and erosion rates comparable to those for a 10%–24% slope are employed. Optimal strategies for different values of the soil quality weight, λ, and for different levels of available soil moisture and solum depth are determined. The present value of net returns

depends upon the level of soil moisture as well as solum depth. For a solum depth of 20 centimeters the present value of net returns for the strategy associated with $\lambda = 0.0$ (no weight on soil quality) increases from approximately $1,140 per hectare to $1,390 per hectare as available spring soil moisture increases from the lowest to the highest level; for $\lambda = 0.8$, the associated range is $1,050 per hectare to $1,340 per hectare.

The optimal strategies and critical soil moisture values also change as solum depth declines. For example, the strategy for a producer with $\lambda = 0.4$ is to employ tillage fallow whenever available soil moisture is below 2.5 centimeters, use chem-fallow when it is between 2.5 centimeters and 5.0 centimeters, and plant spring wheat whenever spring soil moisture is greater than 5.0 centimeters, but only when solum depth exceeds 12.8 centimeters. For solum depths between 4.4 and 12.8 centimeters, the optimal strategy is to employ chem-fallow whenever available soil moisture in the spring is below 5.0 centimeters and to plant wheat otherwise. Finally, if solum depth is below 4.4 centimeters, the optimal strategy is to employ chem-fallow if soil moisture is below 2.5 centimeters and plant wheat if it is above this level, at least until the present value of net returns becomes negative. No allowance is made for alternatives other than fallowing and planting of spring wheat. It is likely that land will be turned into pasture at low solum depth levels, although this was not investigated in the model.

In summary, the optimal strategies obtained from the Markov decision model indicate that a producer will employ chem-fallow as opposed to tillage or conventional fallow at higher values of λ.[5] For example, at 20 centimeters of soil, the farmer with $\lambda = 0.6$ will chem-fallow when soil moisture is less than 5.0 centimeters, while a producer with $\lambda = 0.0$ will employ tillage fallow whenever soil moisture is below 7.5 centimeters. Further, at lower solum depths, the farmer concerned with soil quality will tend to crop at lower levels of soil moisture and use chem-fallow more frequently compared with the producer who does not share this concern for soil quality.

The flexcrop results can be used to estimate how long it takes to erode a given amount of soil. Given an initial soil moisture level of 11.25 centimeters, flexcrop strategies take between 129 and 200 years to erode 32 centimeters of solum down to 4 centimeters, depending upon assumptions about the importance farmers place on solum depth in their objective function (Chinthammit).[6] If a farmer's only concern is with maximizing net returns, the optimal flexcrop strategy will erode 28 centimeters of solum in approximately 129 years. When soil quality is a concern (higher values of λ), the rate of erosion is lower. However, the major benefits of soil conservation are obtained without requiring a steep trade-off between returns and concern for soil quality because erosion time paths for $\lambda > 0.4$ are almost identical to those for $\lambda = 0.4$.

The cropping strategy that prevails in the study region is a fixed, two-year, wheat-fallow rotation. The main reason for the dominance of this rotation is that, while expected returns are lower, the variance of return is also lower. For a slope grade of 10%–24%, the fixed crop rotation erodes away 28 centimeters of solum in about 73 years compared to 129 years for the profit-maximizing flexcrop rotation and 199 years for a flexcrop rotation obtained when $\lambda = 0.6$.

The Trade-off Function

Aggregate values of each of the profit and soil quality objectives can be derived for each level of λ and plotted to give the trade-off function. The trade-off functions in figures 2 and 3 correspond to (current) solum depth levels of 20 centimeters and 10 centimeters, respectively, and average spring soil moisture (11.25 cm). For a solum depth of 20 centimeters, optimal choices change very little over the range $0 \leq \lambda \leq 0.3$, but they decline sharply thereafter, until $\lambda = 0.6$; the largest trade-offs occur in the range $0.3 \leq \lambda \leq 0.6$. For a solum depth of 10 centimeters, the comparable range is approximately $0.1 \leq \lambda \leq 0.8$. This indicates that, at 20 centimeters of solum depth, a producer must have a substantial concern with soil quality before agronomic practices are clearly distinguishable from profit-maximizing practices. At lower solum depths (fig. 3), the stewardship concern does not need to be as great in order to be able to distinguish stewardly agronomic activities.

The loss in profit when decisions based on

[5] In all of the scenarios investigated (but not reported here), conventional summerfallow was no longer a viable strategy whenever $\lambda > 0.5$.

[6] It is assumed that after 4 cm of solum depth the land will no longer be used for cropping.

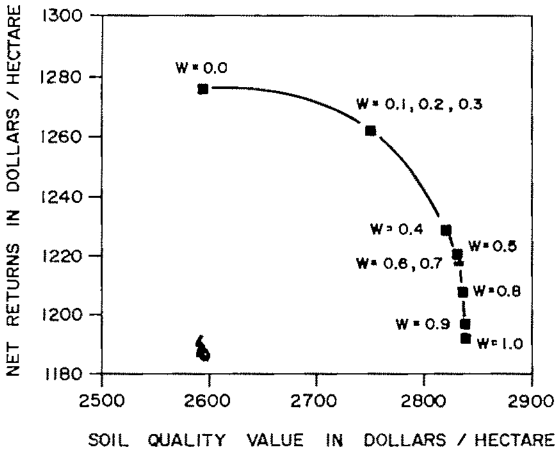

Figure 2. Trade-off function derived at solum depth = 20 centimeters and soil moisture = 11.25 centimeters

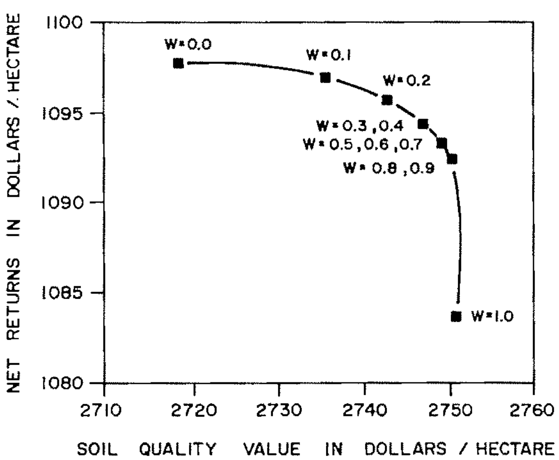

Figure 3. Trade-off function derived at solum depth = 10 centimeters and soil moisture = 1.25 centimeters

soil quality are taken can be calculated using the method described by Thampapillai and Sinden (p. 1033). The opportunity costs of the Q objective at 20 centimeters and 10 centimeters of solum, and at 11.25 centimeters soil moisture, are provided in table 5. The opportunity cost measures the sacrifice in discounted net returns required to achieve the soil quality associated with a particular level of stewardship. The opportunity costs at higher solum depth are greater than those at lower levels of solum depth. For $\lambda = 0.4$, the opportunity cost is $41.22 per hectare when solum depth is 20 centimeters. If a farmer has 10 centimeters of solum, the opportunity cost is $4.53 per hectare. When $\lambda = 0.9$, the opportunity cost in present value terms is $73.13 per hectare for the high solum depth (20 cm) and $5.69 per hectare at the lower solum depth (10 cm). The actual point on the transformation curve chosen by a producer, or the amount of profit he is willing to sacrifice, depends upon his utility function.

Conclusions

Farmers generally say that they are concerned about soil stewardship, but the results presented here indicate that it will take a substantial concern for soil quality before one observes a change in agronomic practices. Further, soil-conserving practices require sacrifices in profits that tend to be quite small, usually less than 5% of net returns. To the extent that our model is representative of actual farming practices and conditions, the results suggest that educating farmers about cropping alternatives and the low costs associated with soil conservation may yield sub-

Table 5. The Opportunity Cost of Soil Quality (Soil Moisture at 11.25 cm)

stantial improvements in the study region's annual soil loss. Because the opportunity costs of alternative management practices are also low compared to current government transfer payments, perhaps conservation compliance can be used as a prerequisite to receiving benefits, something that is now not done in Canada.

Four areas warrant further research. (*a*) Farmers in the study region currently do not employ the flexcrop strategy which is used as the basis of our calculations. While the prevailing two-year, wheat-fallow rotation is not optimal from an expected returns point of view (Weisensel), it may be optimal for risk-averse producers. Future research should address the implications of this possibility (Young and Van Kooten). (*b*) Only one crop is considered in the model (spring wheat), and cropping and chem-fallow are the only conservation alternatives considered. The model should be expanded to take into account other crop possibilities (e.g., winter wheat, barley) and other conservation strategies (e.g., strip cropping). (*c*) Only four years of data are available. Except for yield comparisons, the extent to which the data are representative of conditions over a longer period of time is unknown. Even the yield data may not be representative of average yields in the region because the data are from experimental plots where, for example, fertilizer-use recommendations are based on information which may not be generally available on other fields. (*d*) The analysis ignores optimal farmland purchase and machinery replacement (fixed costs). Inclusion of these decision variables would improve the model's ability to represent the real world.

Rural Road Abandonment: Policy Criteria and Empirical Analysis

Cathy A. Hamlett and C. Phillip Baumel

Deterioration and changing use patterns of the rural road system have coalesced into difficult policy decisions for local government officials. One option for consideration is abandonment of some low-volume roads. A model is developed, using utility maximization and Pareto-optimal criteria, that allows identification of policy criteria for abandonment. The criteria are empirically estimated and 4% to 12% of the roads were found to be good candidates for abandonment without a net social loss.

Key words: network simulation, road abandonment, rural infrastructure, rural roads, social decision making.

Structural shifts in rural America have dramatically changed the types of traffic on the rural road system. Increased farm size has resulted in a major reduction in the number of farms, with the surviving farmers operating on scattered farms, using larger and heavier farm equipment to travel longer distances. In addition, farmers and agribusiness firms are using larger trucks and tractor-wagon combinations to haul inputs to farms and farm output to market. At the same time, the declining farm population has resulted in fewer farm households in the rural areas. Thus, an increasing number of rural road segments no longer provide service to households (Des Moines *Register*).

On one side of the rural road problem is a system serving fewer households but also serving farmers with heavier equipment who must travel longer distances. On the other side of the problem is a system that has been deteriorating for many years. Precise data on the current condition of the local rural roads is limited because no ongoing coordinated data collection system exists, but the most recently available information indicated that 54% of the local rural roads were rated "intolerable" (U.S. Department of Agriculture). Appalachian and Delta states had the highest percentage of intolerable local rural roads (81% and 77%, respectively), while the Northern Plains and Lake States had the lowest percentage of intolerable rural roads (38% and 31%, respectively). Common complaints about local rural roads include (*a*) heavy and overweight vehicles are breaking up road surfaces, (*b*) lack of paved surfaces creates dust and rideability problems, (*c*) widths and other design characteristics are inadequate for today's large farm equipment and heavy trucks, and (*d*) narrow lanes create safety problems.

Major problems also exist with bridges on the local rural road system. Deficient bridges on local rural roads are creating serious safety and traffic constraints. A structurally deficient bridge will not carry a legal load, while a functionally obsolete bridge will carry a legal limit but is too narrow or has other characteristics that do not meet minimum design standards. Nationally, 166,783 bridges, or 55% of all the inventoried off-federal-aid bridges, were deficient (U.S. Department of Transportation 1987). Even this number understates the magnitude of the problem because bridges under 20 feet long were not included in the inventory. Thousands of bridge structures under 20 feet need replacement or rehabilitation (Smith).

The distribution of deficient bridges among states indicates that the off-system bridge problem is national in scope. The states with the highest percentage of deficient bridges are Kentucky, North Carolina, Missouri, Nebraska, South Dakota, Louisiana, New York, and West Virginia. The states with the largest number of deficient bridges are Texas, Iowa, Kansas, Missouri, North Carolina, and Oklahoma. States in the Northeast, Midwest, Southeast, and Southwest are included in the group with a high per-

Journal Paper No. J-12973 of the Iowa Agriculture and Home Economics Experiment Station Project No. 2173.

centage or a high total number of deficient bridges (U.S. Department of Transportation 1987).

The estimated replacement costs for modernization of the rural system are staggering. An Iowa study projected that county-road revenue buying power would cover only 51% of the needs for 1982–2001 period (Iowa Department of Transportation 1983). Yet, public funding increases for rural infrastructure have perennially lagged behind these burgeoning maintenance and reconstruction needs. Local officials face the dilemma of their governments being held legally liable for the condition of the structures without adequate funding to meet reasonable design standards (Chicoine and Walzer 1986). A likely solution to the dilemma will be a reduction in the road system, probably through a combination of several alternatives. One alternative is abandoning low-traffic roads with no property accesses (Baumel, Schornhorst, and Smith). Previous research on benefit/cost estimation relative to rural roads has suggested tentatively that some benefits are gained from rural road abandonment. Several studies, including ones by Hartwig and the Iowa Department of Transportation (1982) have suggested that abandoning roads may lead to cost savings greater than benefits foregone.

Only a small number of studies have attempted to collect data and empirically address the issue of reducing the rural road system. In Pennsylvania, the Department of Transportation identified an Agricultural Access Network, where roads judged to be most important to the rural areas for agricultural product transportation were identified. The nonfarm rural resident, however, was not included in the study.

A circuity-type model was used by Nyamaah and Hitzhusen to estimate the rerouting costs of posting or closing fifteen rural bridges in Ohio. The model showed substantial benefits for selected bridge repair or replacement. Unfortunately, all types of rural traffic, such as farm equipment travel, were not quantified and rerouted after the bridge closing.

Johnson published a theoretical model for estimating the benefits of road improvements. His analysis was conceptual and did not estimate any benefits. The major factors for an accurate benefit measurement are identified in the model as traffic origins/destinations, volumes of traffic, and composition of vehicles. More recently, Shaffer has called for an extensive benefit/cost evaluation of the rural road system. Because rural road abandonment is an important reduction strategy, and because the political implications for local officials are considerable, the following analysis focuses upon road abandonment as a policy option. Closing a road is an unpopular policy option, and a need exists for an objective criteria and analysis to support the decision making.

The model that follows allows analysis of road abandonment policy by identifying theoretical criteria to determine when a road should be abandoned. A method for empirically estimating the criteria is also outlined and the estimation results are reported. Specifically, the objectives of this work are to (*a*) model individual preferences for the road system, (*b*) develop a societal model for road system decisions, (*c*) derive policy decision criteria, and (*d*) empirically estimate the decision criteria.

The Model

The rural road system is a public good, mostly because a person driving on a rural road (or consuming a unit of a public good) does not preclude others from driving on the same road (or consuming the same good) (Samuelson 1954, 1955). Another way to think of the private/public good distinction is that a unit of a private good enters only one person's utility function. A unit of public good enters multiple utility functions. This multiplicity has also been called a joint distribution constraint because supplying a public good to one is not possible without supplying it to others (Musgrave and Musgrave or Cornes and Sandler). Any model of the road system must incorporate this public good aspect.

A utility framework is used to model person j's demand for Q, the rural road system. The individual's utility function, assumed to be strictly increasing in all arguments, smooth, quasi-concave, and twice-continuously differentiable, is represented by

$$(1) \qquad U^j(y^j, x^j), j = 1, \ldots, h,$$

where y^j is a private good or some bundle of private goods, and x^j represents the benefits derived from the road system. A total of h individuals have a demand for the road system being studied.

The translation from the benefit space of x^j to the road system space, Q, is assumed to be strictly increasing, smooth and quasi-concave:

$$(2) \qquad x^j = f^j(Q), j = 1, \ldots, h.$$

Each rural traveler has a function, f^j, that translates the road system, Q, into benefits from the system, and these benefits enter into the individual's utility function as x^j.

The rural road system, Q, is an $n \times 1$ vector of indexes representing all the n roads in the rural system. The distance and quality of the n roads are each represented by an index, q^i, where $i = 1, \ldots, n$. If q^i is one mile of gravel-surfaced road, it could be compared to q^j, one mile of road with a dirt surface. In this case q^i is greater than q^j.

Income considerations constrain the maximization of utility, with the constraint having the following form:

$$(3) \qquad M^j = y^j + t^j(p'Q), j = 1, \ldots, h.$$

Income is spent on the private good, y^j (taken to be the *numeraire,* so $p^y = 1$), and taxes to support Q. The tax system is simple; person j pays t^j, $0 < t^j < 1$, which is proportion of $p'Q$—the cost of the public road system. The value $p'Q$ assumes that an $n \times 1$ vector, p, of road costs is known. The sum of $t^j(p'Q)$ over all h people equals the provision cost for the rural public road system.

A small part of all decisions made by individual j is being explicitly modeled. A separability between the modeled decisions on road provision and those made in other parts of individual j's life is being implicitly assumed, an assumption often used when the modeled good requires only a small proportion of an individual's income and time to consume (Kealy and Bishop). In the income constraint, only the taxes paid for the road system are included, which is an abstraction, though not as extreme as one might think. While a rural resident may not know the exact amount of his or her tax dollars going to support the road system, a perception of the general proportion, however, can be formed by the person.

The next step for policy analysis is to identify the public's preferences for the rural road system. Pareto-optimal criteria are used at the societal decision rule to search for a socially optimal equilibrium, where no one can be made better off without someone experiencing a decline in utility.

For notational clarity, the Pareto model is set up to maximize person 1's utility subject to everyone else obtaining at least a given utility level, U^{oj} where $j = 2, \ldots, h$, and also subject to an aggregate income/consumption transformation function. The h people using the rural road system are arbitrarily numbered from 1 to h. The maximization problem is

$$(4) \qquad \max_{(Y,Q)} U^1(y^1, f^1(Q)),$$

subject to

$$\sum_{j=1}^{h} M^j \geq \sum_{j=1}^{h} (y^j + t^j(p'Q)),$$

$$U^j(y^j, f^j(Q)) \geq U^{oj} j = 2, \ldots, h$$

$$Y \geq 0, Q \geq 0.$$

In (4), Y is an $h \times 1$ vector containing y^1, y^2, $\ldots$, y^h. A linear resource transformation function is assumed, implying constant costs, where the sum over all M^j represents exogenously fixed resources. The Lagrangian form for (4) is

$$L = U^1(\cdot) + \lambda \left\{ \sum_{j=1}^{h} (M^j - y^j) - p'Q \right\} + \sum_{j=2}^{h} \gamma^j [U^j(\cdot) - U^{oj}].$$

The relevant Kuhn-Tucker conditions are as follows:

$$(5) \qquad \gamma^j U_y^j \leq \lambda, y^j \geq 0, y^j \frac{\partial L}{\partial y^j} = 0, \quad j = 1, \ldots, h; \gamma^1 = 1;$$

$$(6) \qquad \sum_{j=1}^{h} \gamma^j U_x^j f_{qi}^j \leq \lambda p^i, q^i \geq 0, q^i \frac{\partial L}{\partial q^i} = 0, \quad i = 1, \ldots, n; \gamma^1 = 1.$$

Note that U_y^j represents $\partial U^j / \partial y^j$ and so forth. Also the sum of t^j over all h people equals one, so t^j drops out of the Lagrangian. Dividing (5) into (6) yields the following:

$$(7) \qquad \sum_{j=1}^{h} f_{qi}^j MRS_{xy}^j \leq p^i, i = 1, \ldots, n,$$

where MRS_{xy} is the ratio of the partial derivative of U^j with respect to x and the partial derivative of U^j with respect to y. Relationship (7) says that the societal rule for a quality/provision decision on road i involves a trade-off between the cost of providing the road (p^i) and the weighted sum of the marginal rates of substitution between the private and public goods for all people.

Consider an abandonment decision relative to road i. To simplify further discussion, the left side of (7) is referred to as b. If b is less than

p^i, then the benefits society gains from the road are less than the cost of providing the road. In this case, road q^i should be abandoned ($q^i = 0$). If b is greater than p^i, then the road should remain in the public system.

For the above decision rule to be useful, a method for estimating the benefits and costs of a road is needed. The next section outlines the methodology for such estimation and the following section reports results from the estimation.

Outline of Empirical Estimation

Equation (7) suggests a comparison of benefits and costs. An estimation technique is needed to capture the marginal benefit accruing to society from a road as well as the cost of providing that road.

Road Benefit Estimation

The sum of everyone's weighted marginal rate of substitution between the road system and the private good must be empirically estimated before policy comparisons can be made. Estimation must capture the value of a marginal change in road system benefits in terms of the private good, y. Measuring an individual's marginal rate of substitution is impossible, but a proxy can be used.

A proxy that has intuitive appeal and empirical possibilities is the change in travel cost incurred by rural travelers as the road system varies. As the road system is reduced through road abandonment, the rural traveler may have to change routes to avoid the abandoned road, and this can be translated into a cost. For convenience, denote the change in travel cost as ΔTC; ΔTC is thus a reasonable proxy for the marginal value a person puts on a road.

Because physically closing a road and measuring the cost to those who have to go around the road would be difficult and costly, a simulation model was used to estimate ΔTC. Traffic flows were simulated, allowing an estimation of travel-cost changes as changes to the road system were made. The rural road system for a given area was represented as a network, and Dijkstra's algorithm was used to find minimum cost routes for the rural travelers (Pautsch, Hamlett, and Baumel).

Dijkstra's algorithm develops the shortest tree by fanning out from an origin node. The advantage of this procedure is that once an arc is part of the tree, it never leaves. Therefore, the shortest route to all nodes within the tree is known. See Mandl or Dreyfus and Law for further discussion.

The policy of road abandonment was then investigated by changing the network (i.e., to abandon a road, remove an arc from the network) and then the simulation model was used to reroute the traffic. Minimum cost routing of each trip was found through the simulation model, and then the cost of traveling on the status quo road system was summed. After altering the network to reflect an abandonment alternative, the traffic was rerouted and the new cost tabulated. The difference in the travel cost of the two solutions is ΔTC, an estimate at the margin of the road system benefits.

The use of this type of proxy assumes that the number, origin, and destination of the traveler's trips remains the same after the policy implementation. Some trip consolidation would probably occur after the road system was reduced and the proxy does not account for such consolidation. A more detailed discussion of the traffic simulation model is presented in Baumel et al. The data needed for the simulation were the origin, destination, frequency, and vehicle used on each trip over a period of time.

Road Cost Estimation

The costs of road provision are represented by p in equation (7), where p is the vector of prices to provide the various index values of road types. For the simulation, road costs per mile and per vehicle-pass for different road-surface types were needed. The cost of providing a specific road is dependent on the structure of the entire road system. Because the price of road maintenance and reconstruction costs are dependent on the number and types of vehicles that travel over the road, investigating the abandonment of the road i must include the additional traffic inherited by adjacent roads when road i is abandoned.

Information from the simulation model was used to estimate the road-provision price. The first run of the simulation model, before the road system was changed, gave estimates of daily traffic on all roads. After a system change, when the traffic was rerouted, daily traffic estimates were also obtained. By calculating the total cost of road provision before and after a policy was implemented, the price of providing road i was estimated. The computer algorithm used to es-

timate the road provision cost is presented in Baumel et al.

Empirical Estimation

For the empirical estimation, three study areas were chosen. All were in Iowa but represented very different rural situations. Each area was 100 square miles. One area, located in Hamilton County, has a high agricultural tax base, a high percentage of paved roads, and relatively few bridges. The second area, located in Shelby County, has a relatively low agricultural tax base, hilly terrain, a low percentage of paved roads, a large number of oil-coated and earth-surface roads, and many bridges. The third area, located in Linn County, has a high agricultural tax base, a high percentage of paved roads, and a large number of nonfarm households commuting to nearby cities.

Primary data were collected on trip origin, destination, frequency, and vehicle used for rural residents in three areas. Data for 1982 on personal and farm-related travel were obtained by personal interviews from a census of households and farms in the three study areas. Farmers whose residences were outside the study area but who farmed land within the area were also contacted for personal interviews.

The questionnaire obtained data on the exact location of each respondent's home, land tracts within and outside the study areas, and the location of all home and field driveways. In addition, the number of yearly trips by vehicle type was obtained for each farm and household. A more detailed description of the primary data collection is in Hamlett, Pautsch, and Baumel.

Cost functions were developed for the numerous vehicles used by the rural residents. A cost per mile value for different surface types was developed for all vehicles (Hanson, Hamlett, and Baumel).

Many origins or destinations of the trips were outside the original 10-mile by 10-mile study area. To incorporate out-of-study area origins or destinations, the network was expanded to include a three-mile border around each study area. The expansion allowed direct routing for many of the out-of-study area trips. Also, border nodes were used for each side of the study area. Some trips were then assigned an origin or destination of the border node, which allowed routing the trip along the least-cost route to one edge of the study area. The goal was to simulate the trip through the study area, not the whole trip.

Prices or costs of providing the road system were constructed by collecting data on maintenance and resurfacing costs of roads and bridges in the three study areas. Provision costs of the road systems included road maintenance, road reconstruction, road resurfacing, bridge maintenance, and bridge reconstruction. Because some of these costs, such as reconstruction costs, occur infrequently, they were annualized and converted to net present values.

Also included in the price of providing a road was the productive value of the underlying land. A local cash rent value was used as a proxy of the land's productivity in the absence of the road.

Policy Evaluation

Once the data had been gathered and compiled and the road system incorporated into the network model, the policy of rural road abandonment could be evaluated.

The simulation model was used to estimate equation (7) for six sets of road abandonments. As was described before, the traveler's trips were routed over the status quo network and the travel costs summed along with road provision costs. For evaluation of an abandonment policy, each road in the set to be abandoned was removed from the network, travelers then were routed over the altered network, and again costs were summed. The difference in costs between the two states provided an estimate for equation (7). Decisions on roads to include in the abandonment set were made in conjunction with the county engineers who had responsibility for the roads in the study areas. Sets of roads, rather than single roads, were investigated because of the expense of each model estimation. The to-be-abandoned roads did not deny access to any residence or field.

Table 1 contains the estimation results for the six sets of abandonments. The relationship between benefits and costs differed for each policy alternative. For the first set of roads abandoned in each study area, the price of providing the roads was greater than the total individual and public benefits gained from having the roads in the system. Thus, the decision criteria indicated that these sets of roads should be abandoned. In the Linn and Shelby County areas, additional sets of roads were abandoned and the benefits/costs estimated. These three additional abandonments resulted in the benefits being greater than the costs, indicating that abandonment is not optimal.

Table 1. Decision Criteria Estimation for Rural Road Abandonment

Policy Alternatives	Benefits (b) from Roads Remaining in System	Costs Saved (p^i) from Abandonment	Difference (Benefit-Cost)
	($)		
Linn County study area[a]			
L_1	29,014	29,382	−368
L_2	28,138	19,534	8,604
Shelby County study area[b]			
S_1	39,276	52,030	−12,754
S_2	78,436	33,089	45,347
S_3	77,052	16,123	60,929
Hamilton County study area[c]			
H_1	68,521	85,002	−16,481

[a] For policy L_1, 5.25 miles of road were abandoned, and an additional 3.75 miles were abandoned in L_2 (5.25 miles is approximately 4% of the unpaved roads in the study area).
[b] For policy S_1, 9.25 miles were abandoned, an additional 6.75 miles in S_2, and an additional 5.25 miles in S_3 (9.25 miles is approximately 5% of the unpaved roads in the study area).
[c] 17.75 miles of road were abandoned (slightly over 12% of the unpaved roads in study area).

The net savings from abandonment varied by study area. Substantial maintenance and reconstruction costs were saved by the local governments because of the reduction in road system. Because the net savings were positive for the first abandonment solution in each area, it is clear that some roads are good abandonment candidates. But a high percentage of the roads could not be abandoned without a net loss to society. On a per mile–per year basis, the net savings ranged from $70 for the first 5.25 miles abandoned in Linn to $1,379 for the first 9.25 miles abandoned in Shelby County. Abandoning 17.75 miles of low-volume, no-access roads in Hamilton resulted in a net benefit of $16,481, or $929 per mile abandoned. The net savings from abandonment were relatively low because the trips that would normally travel over the abandoned roads were rerouted, resulting in an increased travel cost.

Comparisons of the estimations for L_2, S_2, and S_3 to L_1, S_1, and H_1 show that as more roads are abandoned, the costs to travelers increase much faster than the savings in road-provision costs. Most of the S_2 roads had between ten and thirty average vehicles per day, and the L_2 and S_3 roads generally had more than thirty vehicles per day.

Conclusions

A utility-maximization model provided a criterion for deciding whether a road should be abandoned or left in the public system. The criterion involves comparing the sum of weighted individual marginal rates of substitution between road benefits and private goods to the price of providing a road. If total benefits of a road are less than the cost of providing that road, the optimal policy decision is to remove the road. Benefits that are larger than the costs indicate a road that should remain in the public system.

A procedure for estimating the benefits and costs was outlined. The benefit estimation involves collecting travel information from the rural residents and using a simulation model for routing trips. The empirical estimation involved a large primary data collection effort and focused upon three midwestern study areas. Benefit and cost estimation was done for six abandonment alternatives. Three of the six sets of roads evaluated for abandonment were identified as good candidates for abandonment. The estimation indicated that between 4% and 12% of the roads in the areas studied could be abandoned with a net gain to society. Thus, only a relatively small number of miles of abandoned low volume rural roads would produce greater cost savings to local governments than additional costs to the traveling public.

Local government officials, however, may be reluctant to make even small reductions in the local rural road system because of political concerns along with legal costs and court-awarded damages. Thus, there is a need for legislation to reduce the political and financial liability from abandonment. Legislative changes could include denying claims to an individual if the road proposed for abandonment is a second access, placing an upper limit on damage claims, permitting local governments to withdraw or revise a proposed abandonment if a court appeal may

result in an excessive damage award, or authorizing the appointment of committees to develop and implement abandonment proposals to relieve elected officials of the political liability.

The small amount of economically sound road abandonment, however, is not likely to solve completely the local government financial problem of providing rural road access. Other alternatives to road abandonment that should be evaluated for potential net cost savings include lowering maintenance on roads that serve only access to farm fields, converting dead-end and other low-volume roads to private drives, and closing rather than reconstructing some bridges on low-volume rural roads. The theoretical model could be expanded to allow development of other policy criteria (Hamlett). Criteria for returning roads to private ownership and reducing the maintenance levels on some roads could be easily developed from the model. The return-to-private-ownership option would involve separating term b into the benefits associated with the individuals who would own the road and those benefits accruing to the rest of society. If society benefits are low but the individual benefits are high, the road would be a likely candidate for removal from the public system. The other policy alternative, reducing maintenance levels would have the effect of lowering p while also increasing travel cost.

Using the Wrong Discount Rate to Allocate an Exhaustible Resource

John Rowse

What are the social welfare implications of using the wrong discount rate to allocate an exhaustible resource? Utilizing a simple numerical model, it is found that, over the (real) discount rate range of 6% to 9%, the welfare losses of employing a rate no more than 3% different from the social rate are small and decline as the social rate rises, even for stringent supply circumstances. However, substantial transfers of surplus between producers and consumers occur as the improper rate deviates from the social rate. Other issues such as income distribution immediately loom larger when a discount rate is chosen.

Key words: control theory, discount rate choice, exhaustible resources.

The discount rate has long been recognized as critical for determining the efficient allocation of an exhaustible resource. Heretofore, however, the social welfare losses from using an improper rate have not been measured. In this paper the social welfare losses are quantified using a simple numerical model with two different sets of parameters. The model (Chapman) features a time-invariant linear demand function, constant marginal production costs, a known exogenous stock, an endogenous exhaustion date, and endogenous prices and allocations. The model is set forth in the next section, and the basic formulas are derived; then, the base case and sensitivity results are presented and interpreted. Concluding remarks are provided in the final section.

The Model

The demand function is linear and stationary and its inverse or willingness-to-pay (WTP) function is specified by $p(y) = \beta_2 - \beta_1 y$, where y is the consumption rate, p the price, and β_1 and $\beta_2 > 0$. The known resource stock is S, and the marginal cost of production α is constant for all units. The social net surplus on consumption of unit y is $p(y) - \alpha$, and hence the aggregate net surplus ns on consumption of y units is

$$(1) \qquad ns(y) = \int_0^y (p(x) - \alpha)\,dx = \beta_2 y - \beta_1 y^2/2 - \alpha y.$$

Discounting at rate r, the present value at time 0 of social welfare through time t is

$$(2) \qquad SW^r(t) = \int_0^t ns(y)\,e^{-rs}\,ds.$$

Superscript r emphasizes the dependence of SW on the discount rate. With slight notational changes from the original formulation, Chapman's problem is to find the consumption path $y_c(t)$ and exhaustion year T_r to:[1]

$$(3) \qquad \left[\begin{array}{l} \text{Maximize } SW^r(T) = \displaystyle\int_0^T \left\{\int_0^{y(t)} [p(y) - \alpha]\,dy\right\} e^{-rt}\,dt, \text{ subject to} \\ p(y) = \beta_2 - \beta_1 y;\ y(t) = \dfrac{dX(t)}{dt};\ \displaystyle\int_0^T y(t)\,dt = X(T) \le S; \\ p, y \ge 0; \text{ and } py - \alpha y \ge 0. \end{array}\right.$$

John Rowse is a professor in the Department of Economics, University of Calgary.

The author is grateful for the research support provided by Energy, Mines and Resources Canada.

Helpful comments on earlier versions of this paper were received from Richard Gordon, John Hartwick, Alan MacFadyen, Campbell Watkins, and two anonymous reviewers.

[1] A similar framework has been employed by others. For example, this same model with $\beta_1 = 1$ is used by Gordon.

If the demand extinction price β_2 exceeds the marginal cost α—an assumption adopted here, then the stock S will be completely exhausted.

The optimal solution consists of several elements. The efficient depletion (competitive-market) path is

$$(4) \quad y_c^r(t) = \beta_3 - \beta_3 e^{r(t-T_r)} \quad 0 \le t \le T_r,$$

where $\beta_3 = (\beta_2 - \alpha)/\beta_1$, and the equation determining T_r is

$$(5) \quad T_r + e^{-rT_r}/r = S/\beta_3 + 1/r.$$

An analytical solution for T_r is not possible; but, given S, β_3, and r, this equation has a single root for T_r, which can readily be found by Newton's method. Substituting $y_c^r(t)$ into the WTP function and simplifying yields the efficient price trajectory:

$$(6) \quad p_c^r(t) = \alpha + (\beta_2 - \alpha)\, e^{r(t-T_r)} \quad 0 \le t \le T_r.$$

At time t the efficient price consists of the marginal cost plus a user cost (Dasgupta and Heal, chap. 6). Hence the second term on the right-hand side of (6) specifies user cost as a function of time.

Substituting $y_c^r(t)$ into (1), then substituting $ns(y)$ into (2), integrating from 0 to T_r and simplifying yields maximum social welfare:

$$(7) \quad SW_c^r(T_r) = \beta_1\beta_3^2(1 - e^{-rT_r})^2/2r.$$

Unit producer surplus is the difference between price and marginal cost. Thus the producer surplus associated with consuming y units is

$$(8) \quad ps(y) = [p(y) - \alpha]\, y = \beta_2 y - \beta_1 y^2 - \alpha y.$$

Discounting at rate r, the present value at time 0 of aggregate producer surplus through time t is

$$(9) \quad PS^r(t) = \int_0^t ps(y)\, e^{-rs}\, ds.$$

Substituting $y_c^r(t)$ from (4) into (8), then substituting $ps(y)$ from (8) into (9), integrating from 0 to T_r and simplifying yields the producer surplus associated with the efficient depletion path:

$$(10) \quad PS_c^r(T_r) = \beta_1\beta_3^2\,[e^{-rT_r}(rT_r - 1) + e^{-2rT_r}]/r.$$

Finally, consumer surplus is

$$(11) \quad CS_c^r(T_r) = SW_c^r(T_r) - PS_c^r(T_r).$$

Using the Wrong Discount Rate

What happens when the discount rate changes? Clearly from (5), when r changes, T_r changes. It is easily shown that

$$(12) \quad dT_r/dr = -[e^{rT_r} - (1 + rT_r)]/[r^2(e^{rT_r} - 1)].$$

Therefore $dT_r/dr < 0$ and a higher discount rate speeds exhaustion. Furthermore, because $d(rT_r)/dr = Se^{rT_r}/[\beta_3(e^{rT_r} - 1)] > 0$ from (5), near-term user costs in (6) shrink with r, and thus near-term consumption rates increase with r (Hartwick and Olewiler, p. 68). However, if the marginal cost varies either with the discount rate or with the production rate, then these inferences are not possible (Gordon, Watkins, Farzin).

If the allocation problem is solved using discount rate $w \ne r$, then substituting w for r in (4) yields the optimal consumption trajectory:

$$(13) \quad y_c^w(t) = \beta_3 - \beta_3 e^{w(t-T_w)} \quad 0 \le t \le T_w,$$

and T_w can be found by substituting w for r in (5) and solving for T_w. How does this trajectory perform relative to $y_c^r(t)$? Substituting $y_c^w(t)$ into (1), $ns(y)$ from (1) into (2), discounting at rate r, integrating from 0 to T_w, and simplifying yields

$$(14) \quad SW_c^{w:r}(T_w) = \begin{bmatrix} \mu[1 - e^{-rT_w}(1 + rT_w)]/r, & w = r/2 \\ \mu[1 - e^{-rT_w}]/r + \mu e^{-2wT_w}[1 - e^{(2w-r)T_w}]/(2w - r), & w \ne r/2 \end{bmatrix},$$

where $\mu = (\beta_2 - \alpha)^2/(2\beta_1)$. The notation $w{:}r$ indicates that rate $w \ne r$ is used when the correct rate is r. Moreover, substituting $y_c^w(t)$ into (8), $ps(y)$ from (8) into (9), discounting at rate r, integrating from 0 to T_w, and simplifying yields the corresponding producer surplus:

$$(15) \quad PS_c^{w:r}(T_w) = \begin{bmatrix} -2\mu e^{-2wT_w}(1/w + T_w) + 2\mu e^{-wT_w}/w, & w = r/2 \\ 2\mu e^{-wT_w}[e^{(w-r)T_w} - 1]/(w - r) - 2\mu e^{-2wT_w}[e^{2w-r} - 1]/(2w - r), & w \ne r/2 \end{bmatrix}.$$

Finally, consumer surplus associated with $y_c^w(t)$ is

$$(16) \quad CS_c^{w:r}(T_w) = SW_c^{w:r}(T_w) - PS_c^{w:r}(T_w).$$

Because $y_c^r(t)$ is the unique maximizer for (3), $SW_c^{w:r}(T_w) < SW_c^r(T_r)$ for all $w \neq r$. But how far $SW_c^{w:r}(T_w)$ is below the maximum social welfare must be answered numerically for particular values of the model parameters. The approach is as follows. First, given r, solve (5) for T_r, then evaluate $SW_c^r(T_r)$ using (7). Second, given $w \neq r$, substitute w for r in (5) and solve for T_w, then evaluate $SW_c^{w:r}(T_w)$ using (14). Compare this level of social welfare with the maximum social welfare. Complete this second step for several different values of w. Finally, because the social discount rate is not known, repeat both steps for different values of r as well.

Base Case Results

Chapman's parameter values have been adopted for the base case.[2] The demand extinction price of \$75 per barrel can be viewed as the cost of backstop supplies 3.75 times the cost of depletable crude, and demand can also be viewed as shifting completely to these supplies when crude oil is exhausted. Moreover, the stock will support 54.05 years of consumption at a price equal to marginal cost; hence, the stock is relatively large, and exhaustion is not an immediate concern.

Table 1 specifies the character of the efficient depletion paths for discount rates ranging from 3% to 12%. This range of r likely includes the social discount rate and captures both the 5% and 10% rates used in some exhaustible resource models (Daniel and Goldberg, Manne). At a 3% discount rate, the stock lasts 84.76 years and the initial price and consumption rate are, respectively, \$24.33 per barrel and 20.27 billion barrels per year. Consumption at this rate is sustained for nearly a decade, declines slowly, then falls more rapidly. By contrast, for the 12% discount rate, the stock lasts 62.37 years, the initial price is \$20.03 per barrel (17.67% below that of the 3% rate), and the initial consumption rate is 21.99 billion barrels per year (8.49% above that of the 3% rate). Consumption is sustained at this rate for nearly four decades, then declines rapidly. For the 12% rate, user costs are very small for $t = 0$ because the initial price is close to marginal cost.

Several observations are immediate. First, because of the relatively large stock size, the differences between the 3% and 12% solutions, while not small, are not vast for the first three decades. This outcome confirms that the depletion problem is not a pressing one for Chapman's parameter values. Second, the major changes in depletion paths occur when a low discount rate is increased by one percentage point rather than when a high discount rate is increased by this amount. This is partly because a one-percentage-point rise in the discount rate is proportionately greater at a low discount rate than at a high discount rate.[3] Third, the consumption paths for discount rates in the range of 9% to 12% are remarkably similar.[4] Consequently, if the social discount rate lies in this range, but a rate different from the social rate is used which still lies in this range, then effi-

[2] With y measured in billion barrels/year, his specific parameter values were: $\beta_1 = 2.5$ (\$/barrel per billion barrels/year), $\beta_2 = 75.0$ (\$/barrel), $\alpha = 20.0$ (\$/barrel) and $S = 1189.0$ (billion barrels). Because β_2 exceeds α, complete exhaustion is assured.

[3] This cannot be the sole reason. For example, raising the discount rate from 3% to 4% (a 33% increase) cuts the stock life by 6.82 years (or 8.05%), while raising the discount rate from 9% to 12% (also a 33% increase) cuts the stock life by 2.75 years (or 4.22%), a more muted response.

[4] Consumption paths for rates exceeding 12% are very similar to the 12% path. Hence, little is lost by excluding from consideration paths for rates exceeding 12%.

Note. All performance measures are in trillions of dollars. Figures in parentheses are percentage changes relative to the optimal solution for the social discount rate indicated.

ciency losses are apt to be small.

For discount rates in the range of 3% to 12%, performance measures of social welfare (SW), consumer surplus (CS), and producer surplus (PS) are listed in table 2. The entries along the principal diagonal of the table arise when the social discount rate is known and employed. Equations (7), (10), and (11) are used to generate these entries. Off-diagonal entries list performance measures when a discount rate different from the social rate is employed; equations (14), (15), and (16) are used to generate these entries. The figure in parentheses (in exponential notation) beneath each measure indicates the percentage change of the measure from the corresponding social-welfare-maximizing measure. For entries along the principal diagonal, all percentage changes are obviously zero.

For example, for a 3% social discount rate the optimal consumption trajectory is $y_c^{0.03}(t)$ from (4) and SW = \$17.119 trillion (T), consisting of \$11.976 T CS and \$5.144 T PS. For a 5% discount rate the optimal consumption trajectory is $y_c^{0.05}(t)$ and SW = \$11.495 T. If $r = 0.03$ but $w = 0.05$ is used instead, then $y_c^{0.05}(t)$ is suboptimal relative to $y_c^{0.03}(t)$ and using (14) the social welfare for this trajectory is \$17.000 T, consisting of \$13.760 T CS and \$3.239 T PS. These latter entries appear in the third column of the first row. Lost social welfare from using a 5% discount rate instead of the correct 3% rate is thus small—under 1% of the maximum welfare, but the individual surplus measures exhibit much larger absolute and percentage changes: CS rises nearly 15% and PS falls 37%. Similarly, if the true discount rate is 5% but a 3% rate is used instead, then social welfare stands at \$11.426 T, a reduction of only 0.6% from the maximum level. But again, the individual surplus measures experience much larger absolute and percentage changes.

For $r = 0.03$, lost SW increases in percentage terms as w increases. For example, if $w = 0.10$ is used instead, 2.5% of maximum welfare is lost, while CS and PS increase and decrease, respectively, by relatively large proportions. The directional changes to the surplus measures are readily explained. Raising the discount rate reduces near-term user costs in (6) and thus brings the efficient near-term prices closer to marginal cost α, in turn reducing near-term PS and increasing near-term CS. With the higher discount rate, prices rise faster later in time and the adjustments to the surplus measures are reversed. But in present value terms, these distant-term adjustments do not offset the near-term adjustments. Thus surplus is transferred from producers to consumers.

Similar types of adjustments occur for different values of r. When $r \geq 0.06$, if the wrong discount rate deviates no more than three percentage points from the social rate, then lost SW is small—under 1%. Moreover, as the social rate increases, percentage SW losses from using the wrong rate shrink. For higher rates the changes in SW are minuscule because the gains and losses of the two surplus measures are largely offsetting. Furthermore, as suggested by table 1, optimal consumption trajectories for discount rates in the range of 9% to 12% exhibit nearly identical social welfare levels. For such rates the user cost premium of (6) shrinks in the near term, the efficient trajectory approaches the marginal-cost pricing trajectory in the near term, and the present value of producer surplus approaches zero. Distant-term misallocations count little because of the high discount rate.

One further inference is possible. The social welfare losses of using a discount rate double or triple the social rate shrink in percentage terms as the social rate rises. For instance, the welfare losses of using a discount rate twice the social rates of 3%, 4%, 5%, and 6% are, respectively, 1.15%, 0.74%, 0.45%, and 0.27%. The welfare losses of using a discount rate triple the social rates of 3% and 4% are, respectively, 2.23% and 1.36%.

The largest percentage welfare loss (2.92%) occurs when a 12% rate is used, but the social rate is 3%. This result and others imply that, as long as the social rate lies in the range of 3% to 12%, the ten consumption trajectories of table 1 are all near optimal.

That many solutions may be near optimal for a depletable resource model is plausible but not necessarily intuitive. Consider the following modifications to the welfare-maximizing trajectory $y_c^r(t)$. If at time t_1 consumption is reduced by a small amount Δ, then net surplus declines during t_1. But Δ is available to augment consumption at some other time t_2, thereby increasing net surplus. The resulting consumption trajectory must yield lower social welfare than $y_c^r(t)$, but intuition alone cannot predict whether these adjustments reduce welfare by a little or by a lot. An identical argument holds for other similar adjustments to $y_c^r(t)$. Only a numerical approach can determine the size of the losses. Rowse (1988) argues that the reduction to social welfare of deviating from the optimal depletion trajectory—even substantially—may be small, much smaller than the current emphasis on ef-

ficiency in the literature would implicitly suggest.

Sensitivity Analysis

To explore the sensitivity of the results, the analysis is replicated by decreasing the stock size by 90% to 118.9 billion barrels and increasing the demand extinction price β_2 to \$100 per barrel. The increase in β_2 constitutes a substantial outward shift of the linear WTP function (each intercept increases by a third) and, if crude is priced at the marginal cost of \$20 per barrel to exhaustion, the stock lasts only 118.9/32 = 3.72 years, compared with 54.05 years previously. Furthermore, the rise in β_2 represents a rise in the cost of backstop supplies to five times the marginal cost of conventional crude.

Table 3 specifies the character of the new optimal consumption trajectories. Exhaustion occurs much sooner for all trajectories, and the relative differences among them are much greater than before. For instance, for a 3% social discount rate, exhaustion occurs at year 17.08; while for a 12% rate, exhaustion occurs at year 9.33. It is also apparent that user costs for all trajectories are substantial at $t = 0$.

Table 4 indicates the social welfare losses from using the wrong discount rate. Although the percentage losses are larger than before, the changes are surprisingly muted. For instance, if the social rate is 3% but a 10% rate is used instead, welfare is reduced by only 4.48%, less than double the base case loss. In view of the more stringent supply circumstances, this loss is remarkably small. As before, in absolute and percentage terms the transfers between *CS* and *PS* are much larger between solutions than the changes to *SW*. Moreover, similar patterns recur. If $r \geq 0.06$, then deviations of no more than 3% from the social rate reduce welfare by 2% or less. Furthermore, if $r \geq 0.08$, percentage losses are under 1% if the wrong rate deviates by no more than 3% from the social rate. Finally, using a discount rate double or triple the social rate yields losses that shrink in percentage terms as the social rate rises.

Concluding Comments

In this paper the social welfare implications of using the wrong discount rate to allocate an exhaustible resource were examined using a simple numerical model. Principal findings are (*a*) the percentage welfare loss is small if the wrong rate is close to the social rate, but even discount rates differing from the social rate by as much as 3% reduce welfare very little; (*b*) the losses are dominated in absolute and percentage terms by the transfers of surplus between consumers and producers; and (*c*) the percentage losses from using a discount rate double or triple the social rate shrink as the social rate rises.

Given the heterogenous circumstances of different depletable resources, the question addressed in this paper may not have a single unambiguous answer. Yet, several arguments favor the generality of the findings. First, the sensitivity analysis represents an extreme case of supply stringency and still yields small percentage welfare losses from using the wrong discount rate. It is unlikely that a more elaborate model exhibiting much less stringent supply circumstances could yield large welfare losses from using an improper rate. Second, the results arise because there are many near-optimal solutions to the depletion problems considered (Rowse 1988). Hence, adopting a more elaborate computational framework may not yield different results. Finally, analysis with a computationa

Note. All performance measures are in trillions of dollars. Figures in parentheses are percentage changes relative to the optimal solution for the social discount rate indicated.

model embodying several important real-world complexities yields similar findings (Rowse 1989).

Although no firm claim of generality can be asserted, the results offer some comfort to practitioners because the efficiency losses from using a rate not too different from the social rate appear small. Yet the substantial transfers of surplus between consumers and producers when the wrong rate is used imply that income distribution considerations may bear on the discount rate choice. More generally, because most exhaustible resource allocation problems are actually multicriterion problems and not single-criterion problems, the findings also suggest that the current emphasis on maximizing conventional social welfare in exhaustible resource models should be widened to embrace secondary and tertiary criteria. Alternatively, maximizing the sum of consumer plus producer surplus as the only social welfare goal may be a frail reed to lean upon for allocating an exhaustible resource among competing generations of consumers.

On the Political Economy of Public Good Inputs in Agriculture

Harry de Gorter and David Zilberman

The paper analyzes two elements in explaining and prescribing the level of cost-reducing "public good" inputs in agriculture: the distribution of political influence and the economic properties of markets. The incidence of costs/benefits of alternative cost-sharing arrangements between taxpayers and producers is compared to the social optimal and competitive outcomes. Although one group could lose, we focus only on situations of a Pareto improvement. The model predicts why some sectors have relatively more public versus private research funding and why the degree of underinvestment varies across sectors. The observed underinvestment in agriculture may be due to the political power of farmers, inelastic demand, and highly productive public good inputs.

Key words: political economy, public good inputs, public versus private financing.

Agriculture employs cost-reducing inputs that are "public goods," including direct technological inputs (research and development—R&D), the production and distribution of knowledge (information and education), and water facilities (dams and canals). A standard conclusion is that underinvestment in such public good inputs will occur under perfect competition because individual firms cannot appropriate the entire economic benefit. This has led to the emergence of other institutional arrangements to provide the public goods in agriculture including government provision financed by general tax revenues and farm group "collusion." The latter includes instances where growers' associations finance and manage the provision of public goods, leading to collective action in the input market but not necessarily in the output market.[1]

This paper analyzes and evaluates the choice of public good input levels under these alternative arrangements from a political economy perspective.[2] Studies on the economics of public good inputs have focused mostly on the impact of imperfect market structure on R&D perfor mance (Kamien and Schwartz). Little attentio has been given to conceptual analysis of the im pact of alternative political situations and insti tutional arrangements on the provision of publi good inputs in competitive industries. These lat ter issues are especially relevant for the agri cultural sector. Indeed, empirical evidence o returns from public research in agriculture le Ruttan to conclude that there is a significant un derinvestment in such research and suggested tha political economy considerations affect the leve of this research.

The framework presented here will attempt t explain these observations by considering thre alternative scenarios. In two of the cases ex amined, the taxpayers finance the provision o the public good.[3] In one of these, the determi nation of the quantity of the public good is con trolled by consumers and, in the other, it is con trolled by producers. These two polar cases se a bound on all possible outcomes whereby th public good is financed by the taxpayer. The thir case is when the producers both finance the pro vision of the public good and determine it quantity. For each of these cases, the resultin level of the public good and distribution of wel fare between groups are compared to the socia optimum and the competitive case with no gov ernment intervention.

The authors thank Gordon C. Rausser for valuable suggestions.

[1] Marketing orders and agreements are often used as legal vehicles to overcome antitrust problems. The many check-off programs at the state and national level for soybeans, corn, and beef are examples of cooperation to invest in R&D.

[2] Gardner and Rausser presented general frameworks for analyzing the political economy of agricultural policies. Studies generating evidence that political and institutional factors are responsible for this suboptimal allocation of resources in agriculture include Guttman, and Huffman and Miranowski.

[3] Consumers and taxpayers are assumed to be identical in thi paper.

The Model

The analysis uses a deterministic, static, and partial-equilibrium model of a closed economy with competitive market conditions. Suppose that consumer preferences are represented by the separable additive utility function $U(q, Z) = U(q) + Z$, where q is the good under consideration and Z is the *numèraire* good. The marginal utility of consuming q is positive and declining, $U_q > 0$, $U_{qq} < 0$.

The cost function facing the industry, $C(q, E)$, depends on output, q, and public good expenditure, E. The marginal cost of output is assumed positive and increasing ($C_q > 0$, $C_{qq} > 0$), and cost is convex in both E and q ($C_{EE} \geq 0$, $C_{EE}C_{qq} - C_{qE} > 0$). It is also assumed that the marginal impact of the public good on cost is nonincreasing with the level of operation ($C_{Eq} \leq 0$). If the public good affects only the fixed cost of production, then $C_{qE} = 0$; if an increase in E reduces variable cost, then $C_{qE} < 0$. To consider alternative scenarios on the incidence of burden of public good expenditures, let α denote the share of the public good expenditure paid by consumers. If the government provides the public good using the taxpayers' money, then $\alpha = 1$. If, however, the firms in the industry collude and finance the public good provision themselves, then $\alpha = 0$. Assume that individual consumers and producers consider α and E as given in determining their consumption and production choices. Thus, consumers would choose q to maximize $U(q, Y - pq - \alpha E)$, where p is output price and Y is income, and producers would choose q to maximize $pq - C(q, E) - E(1 - \alpha)$. The resulting demand and supply relationships are, respectively, $q = D(p) \equiv U_q^{-1}(p)$ and $q = S(p, E) \equiv C_q^{-1}(p, E)$, where D is demand and S is supply. Equilibrium in the product market is obtained when marginal cost equals marginal utility, $C_q = U_q$; thus, equilibrium price and quantities are functions of the public good expenditure and are denoted by $q^*(E)$ and $p^*(E)$.

The marginal effect of an increase in public good expenditures on output is obtained by total differentiation of the first-order condition to yield

$$(1) \qquad q_E^* = \frac{C_{qE}}{U_{qq} - C_{qq}} = \frac{C_{qE}\,\eta^S\eta^D \cdot q^*}{p(\eta^S - \eta^D)},$$

where $\eta^S \equiv S_p \cdot p/q = p/(C_{qq} \cdot q)$ denotes price elasticity of supply and $\eta^D = D_p \cdot p/q = p/(U_{qq} \cdot q)$ denotes price elasticity of demand. Using equation (1) and the total differentiation of the consumer decision rule, $U_q = p$, yields an expression describing the marginal impact of change in public good expenditures on output price,

$$(2) \qquad p_E^* = \frac{C_{qE}}{1 - \eta^D/\eta^S}.$$

The magnitude of the change in price depends on the magnitude of the marginal impact of public good expenditures on marginal cost ($|C_{qE}|$); thus, a larger $|C_{qE}|$ results in a greater horizontal shift in supply, a greater increase in output, and a greater reduction in output price. An increase in public good expenditure will have a stronger output price effect and a weaker output effect as the elasticity of demand is smaller (in absolute value) and a smaller price and output effect as supply is more inelastic.

Introducing $q^*(E)$ and $p^*(E)$ into the profit and utility functions yields equilibrium utility (U) and profit (π) as functions of the public good expenditure, namely, $U^*(E) \equiv U[q^*(E)] + Y - p^*(E)q^*(E) - \alpha E$ and $\pi^*(E) \equiv p^*(E)\, q^*(E) - C[q^*(E), E] - (1 - \alpha)E$.

Differentiation of these functions with respect to the public good expenditure, using $C_q = U_q$ and equations (1) and (2), yields[4]

$$(3) \qquad U_E^* = -q^* p_E^* - \alpha = -C_E \frac{\varepsilon^q}{1 - \eta^D/\eta^S} - \alpha, \text{ and}$$

$$(4) \qquad \pi_E^* = -C_E + q^* p_E^* - (1 - \alpha) = -C_E\left[1 - \frac{\varepsilon^q}{1 - \eta^D/\eta^S}\right] - (1 - \alpha),$$

where $\varepsilon^q = C_{qE} \cdot q/C_E$ is the output elasticity of the marginal impact of the public good on cost.[5] This elasticity, ε^q, is nonnegative; it equals zero when the public good affects the fixed cost of production. However, it may be larger than 1 when the public good affects the variable cost.

[4] To obtain (3), totally differentiate $U^*(E) = U[q^*(E)] + Y - P^*(E)\, q^*(E) - \alpha E$ with respect to E to obtain $(dU^*)/(dE) = -q^*(dP)/(dE) - \alpha$. Then, substituting for $(dP)/(dE)$ from equation (2) which is obtained by totally differentiating the consumer decision rule, $U_q(q) = P(q)$, and solving gives $(dP)/(dq) = U_{qq}$. Total differentiation of the product market equilibrium, $C_q = U_q$, gives $(dq)/(dE) = (C_{qE})/(U_{qq} - C_{qq})$. Combining this with the previous expression for $(dP)/(dq)$ generates equation (2) which is substituted into the expression earlier for $(dU^*)/(dE)$ to give the final form of equation (3) in the text. A similar procedure for the producer decision problem will yield the result reported in equation (4).

[5] Substituting equation (2) into the middle expression of (3) gives $U_E^* = -q^*[(C_{qE})/(1 - \eta^D/\eta^S)] - \alpha$. Multiplying by $(C_E)/(C_E)$ gives the right-hand term in (3) where $\varepsilon^q = (q^* C_{qE})/(C_E)$.

For example, if the cost function is multiplicative and separable in q and E, $C(q, E) = h(q) \cdot q(E)$; then $\varepsilon^q = h_q\, q/h(q) > 1$ by the convexity of the cost function. If the cost function is additive in q and E, $C(q, E) = h(q) - q(E)$; then $\varepsilon^q = 0$.

A marginal increase in the public good input expenditure has four effects. It has a cost-reducing effect measured by $-C_E$; a price-reducing effect equal to the marginal decline in price times the quantity, $q^* p_E^*$; and a consumers' expenditure effect which equals α and a producers' expenditure effect of $1 - \alpha$. Equation (3) suggests that the marginal impact on consumers of an increase in the public good input is the difference between the price-reduction effect, $q^* p_E^*$, and the consumers' expenditure effect, α. Equation (4) suggests that the marginal impact on the producers' welfare of an increase in the public good is the difference between the cost-reducing effect and the sum of the price-reducing effect and the producers' expenditure effect.

When producers control the provision of this public good input, $\pi^*(E)$ is maximized, while $U^*(E)$ is maximized when consumers have the power or influence to determine the level of E. The welfare evaluation of outcomes under alternative institutional arrangements is obtained by using the total surplus function, $W^*(E) \equiv U^*(E) + \pi^*(E)$. This is an appropriate welfare standard because, given resources, Y, and technology, $C(q, E)$, utility from consumption is $W(q, E) = U(q) + Y - E - C(q, E)$. For each E, $W(q, E)$ is maximized when $C_q = U_q$; hence, q behaves according to $q^*(E)$. Welfare as a function of E is given by $W(q^*, E) = U(q^*) + Y - \alpha E + p(q^*)\, q^* - p(q^*)\, q^* - C(q^*, E) - (1 - \alpha) E = U^*(E) + \pi^*(E)$. Differentiation of the welfare criteria function yields

$$W_E^* = -C_E - 1. \tag{5}$$

The optimal public good expenditure occurs at a level where the marginal cost-reduction effect equals the marginal expenditure.

Incidence of Cost/Benefits Under Alternative Allocation Mechanisms

The implications of three alternative allocation mechanisms are examined in this section. Comparisons are made to (*a*) the competitive outcome without the public good and (*b*) the social optimum. The cases considered are the following. (*a*) The government finances the public good via a consumer income tax, and producers determine or influence its level. In this case $\alpha = 1$, and E is determined by maximizing $\pi^*(E)$. This situation has the government providing the public good, while the administrators in charge are being "captured" by producers in the industry. (*b*) Consumers finance the public good through general taxation but determine its level. In this case $\alpha = 1$, and E is determined by maximizing $U^*(E)$. This is the case where government administrators are captured by consumer groups in allocating the level of public good inputs. (*c*) Producers finance the public good and determine its level. In this case $\alpha = 0$, and E is determined by maximizing $\pi^*(E)$. This situation results from collective action by producers in providing the public good.

Because $W^*(E) = \pi^*(E) + U^*(E)$, evaluating π_E^* and U_E^* (which must have opposite signs at the social optimum, E^*) determines the level of the producer optimum, E_1^* relative to the consumer optimum, E_2^*. Because $-C_E - 1 = 0$ at E^*, conditions (3) and (4) yield $U_E^* = -q^* p_E^* - \alpha = -\pi_E^*$ (at E^*). Hence, E_1^* and E_2^* bounds E^* with $E_1^* \gtrless E_2^*$ as $-q^* p_E^* \lesseqgtr \alpha$ at $E^* > 0$. Namely, consumers' (producers') optimum is larger than social optimum which, in turn, is larger than producers' (consumers') optimum if at the social optimum the reduction in consumers' expenditures associated with a marginal increase in E ($-q^* p_E^*$) is larger (smaller) than consumers' share of the marginal expenditure (α). Thus, $E_2^* > E^* > E_1^*$ is more likely to occur with a smaller value of α and a more inelastic demand (via p_E^*). Obviously, when producers finance the public good ($\alpha = 0$), and it tends to reduce price, E_2^* ($= \infty$) $> E^* > E_1^*$. If a perfectly elastic demand curve exists then $E_2^* = 0$ for all values of α (while $E_1^* = 0$ if $\alpha = 1$). The incidence of economic costs benefits is analyzed in detail in the following subsections for each of these cost-sharing mechanisms under alternative economic conditions.

Consumers Finance the Public Good; Producers Determine Its Quantity

Let E^1 denote the public good expenditure in this case. It is nonnegative and maximizes the producers' profit for $\alpha = 1$. In this case the marginal impact of an increase in the public good expenditure on the producers' profit is the difference between the cost-reduction effect and the price-reduction effect. Using equation (4),

$$(6) \qquad \pi_E^* = -C_E + q^* p_E^* = -C_E\left[1 - \frac{\varepsilon^q}{1 - \eta^D/\eta^S}\right].$$

Assuming concavity of profit in E and q, the public good will be provided ($E^1 > 0$) as $1 - \eta^D/\eta^S > \varepsilon^q$. The exact quantity of the public good is determined at a level where the marginal price-reduction effect ($q^* p_E^*$) equals the marginal cost-reduction effect ($-C_E$). Equation (6) also indicates that the public good expenditures increase as the elasticity of demand is increasing (in absolute value), the elasticity of supply is decreasing, and the output elasticity of the marginal impact of the public good on cost is decreasing. Thus, when producers control the public good provision, more money will be spent on the public good when (*a*) E has a stronger impact in reducing fixed costs as opposed to variable costs, (*b*) the industry is facing a more elastic demand curve, and (*c*) the industry lacks the flexibility to adjust its production capacity in response to changes in economic conditions.

Consumers Finance the Public Good and Determine Its Quantity

Let E^2 denote the public good expenditure in this case. It is nonnegative and maximizes consumers' welfare for $\alpha = 1$. Using (3), in this case the marginal impact of an increase in public expenditures on consumer welfare is the difference between the price-reduction effect of a marginal increase in public good expenditures and the expenditure itself, i.e.,

$$(7) \quad U_E^* = -q^* p_E^* - 1 = -C_E\frac{\varepsilon^q}{1 - \eta^D/\eta^S} - 1.$$

Assuming concavity of consumer welfare in E, equation (7) implies that the optimal quantity of the public good is determined by equating the marginal price-reducing effect with the marginal expenditure (at $E^2 > 0$, $-q^* p_E^* = 1$). Hence, the optimal outcome can be summarized by $E^2 > 0$ as $-C_E > (1 - \eta^D/\eta^S)/(\varepsilon^q)$.

Because $C_E < 0$, it follows that public good expenditures increase as the elasticity of demand is decreasing, the elasticity of supply is increasing, and the output elasticity of the marginal impact of public good on cost is increasing. Thus, consumers will not support any level of public good expenditure if the demand is infinitely elastic, supply is inelastic, or the public good affects fixed cost and not variable cost. On the other hand, when demand is inelastic and the public good expenditure has a strong impact on variable cost in shifting supply to the right, a relatively large volume of public good expenditures will be supported by consumers.

Comparison of Consumer, Producer, and Social Optima: Consumers Finance the Public Good

One can compare E^1, E^2, and E^* under myriad assumptions regarding political power distributions and demand and supply elasticities. The discussion will be limited to situations where the introduction of the public good input improves the welfare of both producers and consumers. Such situations represent a real (not potential) Pareto improvement over the "laissez-faire" case and are more likely to occur and persist than situations when one of the groups is losing relative to no intervention (for a detailed analysis, see de Gorter).

The functions $\tilde{\pi}(E) = \pi^*(E) - \pi^*(0)$, $\tilde{U}(E) = U^*(E) - U^*(0)$, and $\tilde{W}(E) = W^*(E) - W(0)$ denote the welfare gains to producers, consumers, and society, respectively, from the provision of public good inputs. Figure 1 depicts the possible outcomes for scenarios where both $U_E^*(0)$ and $\pi_E^*(0)$ are positive. For small E's, all functions are increasing, and $\tilde{W}$ is larger than both $\tilde{U}$ and $\tilde{\pi}$. In the case where producers' welfare peaks first (figure 1A), the consumers' welfare is increasing at E^1 and $\tilde{U}(E^1) > 0$. Thus, figure 1A occurs when $-C_E > 1$ and indicates that the producers and consumers are better off when the amount of public good provided under the producers' control is positive but is smaller than the social optimum. Figure 1B corresponds to the case whereby $-C_E < 1$ at E^1. Here, the social welfare curve peaks before the producers' welfare curve ($E^1 > E^*$). In such cases, consumers' welfare under producers' control of the public good provision may be larger (as depicted here) or smaller than under competition with no public good provision. Figure 1B also suggests that in this case both the producers' and consumers' welfare improves when consumers control the public good provision.

Because the price-reduction effect embodies the impact of the values of η^D, η^S, and ε^q, the cost-reducing effect is, in essence, a measure of the productivity of the public good. Therefore, the scenarios developed above can be linked to different orders of magnitude of demand elasticity and public good productivity given η^S and

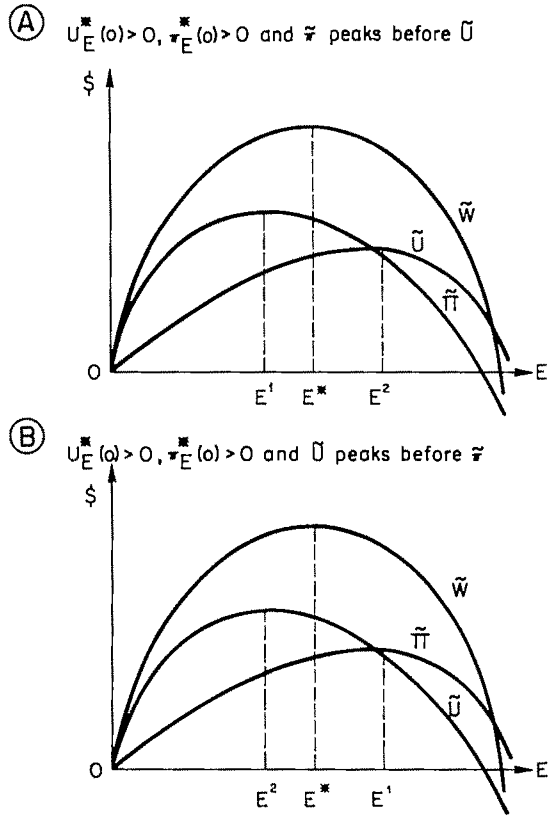

Figure 1. Welfare effects of cost-reducing public good expenditures financed by consumers

ε^q. If public good productivity is sufficiently high and demand elasticity is sufficiently low, a situation may arise where both consumers and producers benefit from the introduction of the public good. One such situation is figure 1A, where the producers' optimum of public good levels is smaller than the social optimum.

Figure 1 sheds some light on the tendency to underinvest in public R&D in U.S. agriculture. Because the demand elasticity for agricultural products is notoriously low and the productivity of public R&D is high (Schultz), the tendency to underinvest in public agricultural R&D is consistent under these conditions with figure 1A. That suggests that the control of R&D in agriculture may have been strongly influenced by producers. Moreover, figure 1A suggests that, under such a scenario, consumers benefit relative to no intervention; therefore, they should not strongly oppose the producers' control over the quantity of the cost-reducing public good, albeit a suboptimal quantity.

Producers' Finance and Determine Public Good Expenditures

Let $\hat{E}$ denote the public good expenditure in thi case. It is nonnegative and maximizes produc ers' welfare for $\alpha = 0$. Using (4), the margina impact of an increase in public good expendi tures on producers' profit is the difference be tween the cost-reducing effect and the sum o the price-reducing effect and the marginal in crease in expenditure. That is,

$$(8) \qquad \pi_E^* = -C_E + q^* p_E^* - 1 = -C_E\left[1 - \frac{\varepsilon^q}{1 - \eta^D/\eta^S}\right] - 1.$$

The optimal level is determined where the sun of the marginal price-reduction effect and th marginal expenditure is equal to the margina cost-reduction effect. It follows that the publi good expenditures increase as the elasticity o demand is increasing (in absolute value), th elasticity of supply is decreasing, and the outpu elasticity of the marginal impact of the publi good on cost is declining.

Comparing equations (5), (6), and (8), whe producers both pay and control the quantity pro vided, the level of public good cannot excee the social optimum or the producers' optimun of the public good when consumers pay. Indeed, the likelihood of no public good bein provided is now greater when producers both fi nance and control the public good compared t either of the two situations discussed earlier There is no possibility of an oversupply of th public good when the producers pay; at most the producers' optimum (when producers pay can equal the social optimum. The equality o positive $\hat{E}$ and E^* occurs when demand is in finitely elastic, supply is completely inelastic or the public good has no effect on variable cost In any of these cases, the producers' optimun when consumers pay will be higher than the so cial optimum.

Therefore, social welfare will increase (com pared to no intervention) if producers both fi nance and control the level of the public goo investment. Moreover, the consumer can onl benefit from positive levels of the public goo when producers control and pay for it. Thus, i seems socially desirable not to prevent collusio among or collective action by firms in a com petitive industry to provide a cost-reducing pub lic good input.

It is inevitable, however, that the resulting leve of the public good investment is less than th

social optimum, with this divergence being greater in sectors with more inelastic demand curves and more elastic supply curves. Hence, it is not sufficient that a social optimum will be obtained if the government encourages firms to provide the public good themselves by collusive agreements. Indeed, the government would have to intervene and supplement the private levels of cost-reducing input and even more so with higher supply elasticities or lower demand elasticities. This may lead to a crowding out of private investment, so that governments would always have to provide or control directly the total expenditure on cost-reducing public good inputs in order for a social optimum to be attained.

Policy Implications and Concluding Remarks

Historically, government has provided and financed a large part of the public good inputs used in U.S. agriculture. Research and development, water projects, information, extension services, and regional pesticide control are examples. Despite the consensus that agricultural research has been a highly productive form of public investment from a social perspective, there is overwhelming empirical evidence of underinvestment in this research. Moreover, patterns of funding and rates of return from research vary substantially among commodities. The foregoing analysis emphasizes two elements in explaining and prescribing the level of public good inputs in agriculture: the distribution of political influence and the economic properties of the markets involved. It focused on cases where the provision of public good inputs improves the welfare of both producers and consumers (relative to no provision) and thus constitutes a Pareto improvement.

The first institutional arrangement considered is the provision of public good inputs by consumer (taxpayer) financing, which characterizes most research and extension activities in U.S. agriculture. If producers control the level of public good provided and the quantity is smaller than the social optimum, then all groups gain relative to no public good provision. Furthermore, it was found that with inelastic demand and a very productive public good, characteristics historically attributed to U.S. agriculture, there would be a large gap between the producer and social optimum. This may partially explain the tendency for significant underinvestment in public R&D in agriculture.

A second institutional arrangement analyzed is when producers organize to provide the public good themselves. Examples include specialty crop research financed by funds raised through marketing orders, institutional arrangements such as water districts which construct and manage water usage, and pesticide control districts financed by producers. In these cases, consumers always gain, but less public goods are provided than is socially optimal. Moreover, a smaller amount of the public good is provided when producers both finance and control its level compared to situations of taxpayers financing and producers determining its level. This may explain situations whereby producers lobby for the construction of new water transfer or disposal facilities with public monies while refusing or failing to finance such projects themselves when public support is denied. In situations where producers finance an undersupply of the public good, governments may be tempted to augment public provision of the public good inputs. Such augmentation confronts the risk of curtailing the private provision of the public good input and substituting public for private financing which, unless government provides the socially optimal quantity, will still result in an undersupply.

The elasticities of supply and demand determine the deviation of alternative policy interventions from the zero quantity outcome. Elasticities also affect the distribution of welfare between groups under alternative cost-sharing arrangements. One plausible hypothesis in explaining the historical provision of public goods in agriculture is that producers introduce and promote public good policy intervention to which consumers do not object as long as the latter's welfare is improved (compared to no intervention). Thus, if the demand elasticities are low, there is positive public research at the producer optimum and, at this level, consumers are better off relative to no public good. If the demand elasticity for a commodity is high, then producers would tend to finance and provide public goods themselves because consumers would otherwise lose welfare. This perhaps explains the evidence in studies by Ruttan; and Judd, Boyce, and Evenson, that public research expenditures for major field crops are underfunded relative to livestock products. On the other hand, research on some specialty crops does not receive public funding at all and is supported only by growers' funding obtained through marketing orders. Heuristically, it seems that specialty crops have higher elasticity of demand than livestock products which, in turn, have higher

demand elasticities than field crops.

Our analysis implies that the demand elasticities of specialty crops are high enough that taxpayer-funded research will reduce consumers' welfare. Therefore, there is no support for publicly funded research, and producers must provide it themselves. Elasticities of demand for field crops and livestock may be low enough that consumers' welfare increases with public financing of R&D. If producers control the level of public research whenever it is provided, then they would prefer relatively more research in livestock products (with higher demand elasticities) than in field-crop products.

The analysis in this paper also helps to explain the basic patterns of support of water projects. We observe taxpayers paying for large projects (e.g., the California Central Valley and Federal water projects) which support an industry large enough to face an inelastic demand for the product grown (e.g., the cotton industry in central California). Regional water projects, on the other hand, involve small numbers of farmers such that the demand elasticity for their output is relatively elastic compared to that facing all farmers in the sector. Hence, projects in local water districts are typically controlled and financed by producers.

A Game-Theoretic Model of Endogenous Public Policies

John C. Beghin

Public policies are the equilibrium outcome of a cooperative game among interest groups and the policy maker. This study stresses the interdependence between policies and players' bargaining strengths and derives their comparative statics with respect to a changing economic environment. It also provides a specification of behavioral equations consistent with the underlying bargaining process. An analysis of the political economy of food and agricultural price policies in Senegal illustrates the proposed framework.

Key words: bargaining game, endogenous policies, interest group.

Endogenous public policy is a familiar concept in the agricultural economics literature. Rausser and Stonehouse, and Abbott (1979a) have formulated and estimated policy behavioral equations to analyze changes in policy decisions in response to exogenous shocks. Abbott assumes that domestic price and import policies are influenced by international variables (e.g., world prices, foreign exchange reserves). Rausser and Stonehouse explain policy instruments by variables representing the interest of pressure groups. These policy behavioral equations are essentially partial reduced forms; no structural identification is claimed.

The revealed preference approach (Rausser and Freebairn, Sarris and Freebairn, Paarlberg and Abbott) explicitly acknowledges the influence of pressure groups in the policy process. The policy maker maximizes a weighted objective function reflecting the welfare of lobbying groups and reveals his preferences through the weights he attributes to the different objectives. This approach has been successful in explaining agricultural policies; however, it does not provide a formal structure of the political economy underlying the objective function of the policy maker.

Cooperative game theory provides a formal model of the bargaining process among lobbying groups and the policy maker that leads to the criterion function of revealed preference (Harsanyi 1963, Zusman). This framework has been applied to the political economy of food price policies in Israel (Zusman and Amiad) and Senegal (Beghin and Karp). Rausser, Lichtenberg, and Lattimore summarize these three approaches.

This paper provides a game-theoretic model of public policy formation that determines simultaneously the endogenous policies and bargaining strength and welfare of the interest groups involved. The economic environment (e.g., world prices, fixed inputs) changes and alters the solution of the game, the equilibrium policies, and distribution of bargaining power among players. The purpose of the paper is to explain and predict endogenous policy changes caused by shifts in the bargaining process underlying the policy formation.

The model provides an original way to quantify and predict endogenous policy changes induced by exogenous shocks without resorting to the econometric estimation of behavioral equations. The framework incorporates the structure of the political economy of public policies that is missing in the behavioral equation approach. Signs and magnitudes of the influence of the exogenous shifters on the policies are computed based solely on information yielded by the estimated game. Previous research on endogenous policies assumed fixed weights in the objective function and did not link shocks of the bargaining process underlying policies to changes in these policies. The approach followed in the study makes that link explicit and uses it to predict policy changes.

The derivation of the comparative statics of

John C. Beghin is an assistant professor, Department of Economics and Business, North Carolina State University.

The author expresses his thanks to Irma Adelman, John Harsanyi, Larry Karp, David Zilberman, and two anonymous referees for their comments.

policy responses also indicates which exogenous variables should be included in the specification of behavioral equations. The suggested specification is entirely consistent with a clearly defined bargaining process among interest groups. Comparison of the two sets of estimated multipliers gives complementary insights and an informal check of the validity of the methodology.[1]

The approach is applied to food and agricultural price policy changes in Senegal. Urban dwellers consuming imported cereals, groundnut farmers, and a marketing board with market power are involved in a game to determine consumer prices of cereal imports and producer prices for groundnuts and agricultural inputs. The influences of world prices, the exchange rate, and some other shocks on the bargaining process and on price policies are estimated. The empirical illustration is interesting because the framework rationalizes the adoption of hybrid policies by African governments which resist recommendations from donor institutions to remove distortions (Scandizzo and Bruce). However, the approach is not restricted to developing countries; it is applicable to many other types of contractual agreements and negotiated policies (e.g., European Community—EC—farm policies, tobacco producer prices in Australia, and wage/employment contracts in labor/management bargaining).

The game-theoretic framework is presented in the next section with emphasis on the complementarity of revealed preference and cooperative game theory. The comparative statics of the equilibrium strategies (i.e., the policy instruments) are derived with respect to changes in the predetermined economic environment, and a proper specification for policy behavioral equations is suggested. Then, the framework is applied to the Senegalese case, the gaming situation is econometrically estimated, and the implications of the results are considered.

A Cooperative Game Framework

The bargaining process between pressure groups and the policy maker often leads to enforceable agreements among the players, making plausible the use of cooperative game solutions (Shubik). From the possible solution concepts, the reference point solution is chosen for use in th study (Thomson 1981). Reference points ar payoffs players refer to when they evaluate pay off proposals. The Nash conflict point, d, an the point of minimum expectation, mex, are ex amples of reference payoffs. They are shown i figure 1, for a two-player game, with their co responding solutions u_d^* and u_{mex}^* on the frontie H, of the payoff set, P. Any convex combina tion of these two reference points can be anothe reference point with its solution on the frontie between u_d^* and u_{mex}^*. Once the conflict point i known, the original Nash solution is unique whereas many reference point solutions are pos sible. Thus, fewer solution candidates are ex cluded a priori from being the equilibrium so lution. The latter approach avoids imposin unnecessary rigidity on the model. It is also as sumed that the payoff set and its frontier chang with the economic environment. Hence players payoffs, their bargaining powers, and equilib rium strategies are influenced by exogenou shocks (e.g., world prices and exchange rate)

Friedman, and Thomson (1981) present th axioms characterizing the reference point solu tion as a generalization of the Nash axioms.[2] the reference point meets some regularity co ditions (Thomson 1981), a solution that satisfie the four axioms maximizes the modified Nas product, i.e., the product of players' gains fro reaching an agreement,

$$(1) \qquad \prod_{i=1}^{n} (CV(s(z), z)_i - g(P, d)_i),$$

where $CV = (CV_1, CV_2, \ldots, CV_n)$ is the vect of utilities of payoffs of the n players and be longs to the utility set $P(z)$; $g(P, d)$ is the re erence point of the players; variable s is the vec tor of strategies available to the players; and is the vector of exogenous variables displacin the game.

For P convex and compact, the solution CV satisfies the necessary and sufficient condition

$$(2) \qquad H(CV_1^*, CV_2^*, \ldots, CV_n^*, z) = 0, \text{ and}$$

$$(3) \qquad a(z)_i(CV(s(z), z)^* i - g(P, d)_i) = a(z)_j(CV(s(z), z)^* j - g(P, d)_j) \text{ for all } i,$$

[1] In the attempt to unify the policy behavioral equation methodology and the revealed preference-game theory approaches, we voluntarily omit the imperfect world market aspects of Sarris and Freebairn and others. World prices are assumed given in this approach.

[2] The axiom of joint efficiency requires that the solution, CV lies on the upper boundary, H, of the payoff space. The axiom linear invariance states that the solution to the game obtained by positive affine transformation of players' utility function is the po itive affine transformation of the solution to the original game. T axiom of symmetry insures that indistinguishable players recei the same payoff. The independence of irrelevant alternatives axio says that excluding a point from P, other than the solution or re erence point, does not change the solution to the game.

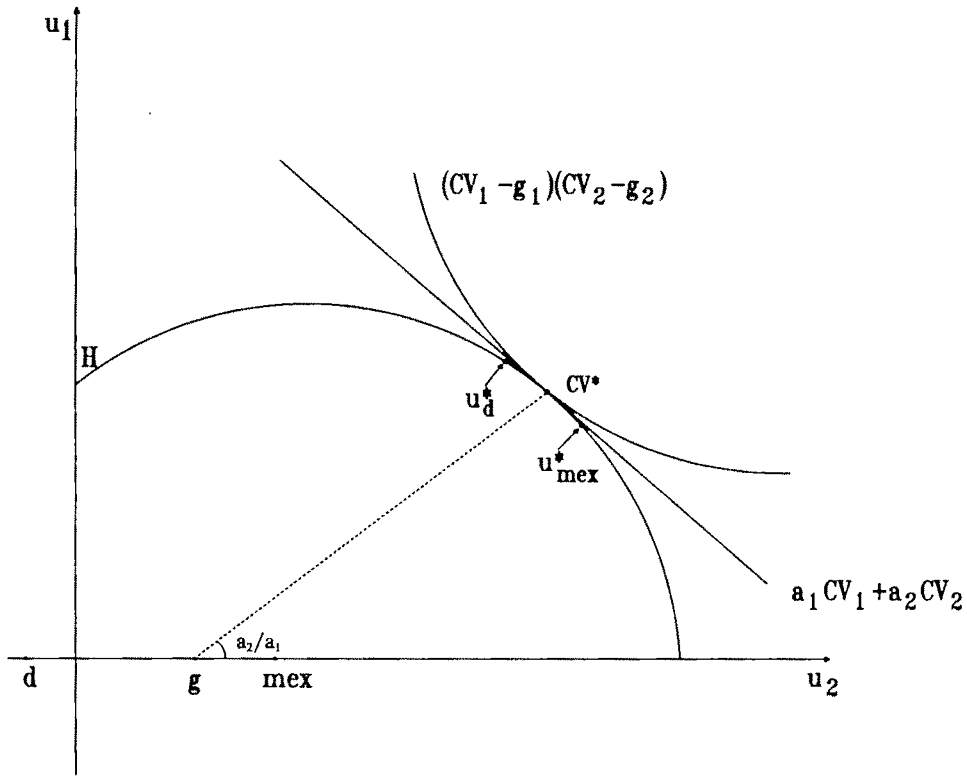

Figure 1. A two-person cooperative game

where $a(z)_i = \partial H(CV^*, z)/\partial CV_i$. The $a(z)_i$'s represent the bargaining-power coefficients of the players; they are the weights of the objective function of revealed preference. And H is the implicit function describing the frontier of the payoff set P. Equation (2) insures that the solution is on the frontier of the payoff set. According to (3), players with prospects of high utility gains have less bargaining power than players with small potential gains from reaching an agreement.

Maximizing (1) is equivalent to maximizing the weighted sum of utilities W:

$$(4)\qquad W = a(z)_1CV(s(z), z)_1 + a(z)_2CV(s(z), z)_2 + \dots + a(z)_nCV(s(z), z)_n.$$

Equation (4) represents the objective function of revealed preference, showing the relative importance of players' utilities. Optimum strategies maximize (4) [or equivalently (1)]. The first-order conditions are

$$(5)\qquad \sum_{i=1}^{n} a(z)_i \frac{\partial CV(s(z), z)_i}{\partial s(z)_k} = 0 \text{ for } k = 1, \dots, t.$$

Figure 1 illustrates equations (1) to (5). The Nash product (1) is the rectangle hyperbola tangent to the frontier H at the solution, CV^*. Conditions (2) and (3) determine the equilibrium solution on the frontier. Player 1 has more bargaining power than his opponent, as indicated by the slope coefficient a_2/a_1 smaller than unity. Moving g to the right horizontally would increase player two's strength and payoff, CV_2. At CV^* the hyperplane tangent to both the payoff set and Nash product is the objective function of revealed preference. First-order conditions (5) push the welfare function outward to the solution tangency point. The convexity of P insures that (2), (3), and (5) are sufficient conditions.

Optimum strategies (policies) are solutions of (5). In general, it is not possible to solve (5) for an expression giving equilibrium strategies as functions of exogenous variables. To derive the comparative statics of the equilibrium strategies with respect to exogenous shocks, the envelope theorem is applied to (5),

(6)
$$\sum_{i=1}^{n}\left[\frac{\partial CV_i}{\partial s_k}\frac{da_i}{dz_j} + a_i\frac{\partial^2 CV_i}{\partial s_k \partial s}\frac{ds}{dz_j} + a_i\frac{\partial^2 CV_i}{\partial s_k\,\partial z_j}\right] = 0;$$

where z_j refers to the jth shock; $\partial^2 CV_i/\partial s_k \partial s$ is the vector of derivatives of $\partial CV_i/\partial s_k$ with respect to s; the scalar $\partial^2 CV_i/\partial s_k \partial z_j$ is the cross derivative of CV_i with respect to s_k and z_j; and the vector ds/dz_j gives the response of the equilibrium strategies s (i.e., the policy variables) to changes in z_j. There are tm equations (6), for t strategies and m shocks. The system of equations for a given shock z_j is

(7)
$$\sum_{i=1}^{n} \left[\frac{da_i}{dz_j} \frac{\partial CV_i}{\partial s'} + a_i \frac{\partial^2 CV_i}{\partial s' \partial s} \frac{ds}{dz_j} + a_i \frac{\partial^2 CV_i}{\partial s' \partial z_j} \right] = 0.$$

Equation (7) is solved for the vector ds/dz_j:

$$(8) \quad \frac{ds}{dz_j} = - \left[\sum_{i=1}^{n} a_i \frac{\partial^2 CV_i}{\partial s' \partial s} \right]^{-1} \cdot \left[\sum_{i=1}^{n} \left[\frac{\partial CV_i}{\partial s'} \frac{da}{dz_j} + a_i \frac{\partial^2 CV_i}{\partial s' \partial z_j} \right] \right] \quad \text{for } j = 1, \ldots, m.$$

The right-hand side of (8) shows the effects of the shock on the bargaining power structure and on the derivatives of the utility functions. The first effect is da/dz_j or $\partial(\partial H/\partial CV)/\partial z_j$; the second one is $\partial(\partial CV/\partial s)/\partial z_j$. The sign of the multipliers ds/dz_j is analytically ambiguous. The multipliers ds/dz_j are computable once estimates of $\partial CV_i/\partial s'$, $\partial^2 CV_i/\partial s' \partial s$, $\partial^2 CV_i/\partial s' \partial z_j$, and da/dz_j are available.

Based on ds_k/dz, a linear approximation of the function relating the kth policy to the shocks, $s_k = f(z)$, is

$$(9) \quad s_k \approx (df(z)/dz)' z + s_k^0 = \beta' z + s_k^0;$$

where s_k^0 is a constant term and β is the vector of multipliers ds_k/dz. Since the multipliers ds/dz are themselves functions of the shocks z, a linear specification of (9) implies an approximation. With an additive error term, (9) provides a specification for the eventual estimation of linear behavioral equations consistent with the bargaining process described by (1) to (5); the multipliers ds_k/dz are the regression coefficients in this case.

The Senegalese Application

The application concerns the political economy of food and agricultural prices in Senegal for the period 1960 to 1980, a period of stability and continuity in institutions and policies. Pressured by international donors, the Senegalese government undertook profound structural reforms i[n] the early 1980s that considerably disrupted pol[-]icies and institutions. Senegalese agricultural an[d] food policies are the outcomes of a bargainin[g] process among economic groups and the gov[-]ernment. Commodity taxation and institution[-]alized market power are the main policy tool[s] to generate and transfer rent from the rural sec[-]tor to government bureaucracies and urban con[-]sumers.

The Senegalese game contains three players[:] farmers in the groundnuts basin growing ground[-]nuts and millet, urban dwellers consuming ric[e] and wheat products, and government agencie[s] determining food and agricultural price policie[s] (hereafter called the marketing board).

Groundnuts is the major cash crop of Sene[-]gal. Since the early 1960s, farmers have bee[n] organized into cooperatives that are unionize[d] and represented in several important state agen[-]cies involved in groundnuts marketing. After in[-]dependence in 1960, small, private groundnut[s] traders were rapidly replaced by a national mar[-]keting board, which has had monopsony powe[r] over groundnuts production since 1964. Farm[-]ers sold their production to the marketing boar[d] through the cooperative. In 1980, the marketin[g] board was dissolved by France as a condition t[o] providing more financial assistance to Senegal[.]

Since 1962, official prices have been an[-]nounced to the farmers before the planting sea[-]son by the marketing board. The prices are es[-]tablished by the Comité des Grands Produits, a[n] interministerial government committee whe[re] cooperatives are present. The political influenc[e] of religious leaders (*marabouts*) is another im[-]portant element in the policy process. The po[-]litical stability in rural areas relies on the he[-]gemony of Moslem leaders who are importan[t] groundnuts producers. Their presence essen[-]tially puts a lower bound on the groundnuts of[-]ficial producer price. This producer price has bee[n] below world price but higher than the level cor[-]responding to full monopsony power. If pro[-]ducer prices are too unfavorable, farmers ca[n] retaliate by changing their crop patterns, smug[-]gling cash crops to bordering countries, default[-]ing on input loans, and withdrawing their po[-]litical support.

Millet is a nontraded rural staple that is pro[-]duced by the same farmers producing ground[-]nuts. Millet and groundnuts compete for the sam[e] inputs. The marketing board was only margin[-]ally involved in millet marketing. Nevertheless[,] millet production and consumption are influ[-]enced by groundnuts and fertilizer-related poli

cies. Millet-market quantity and price are endogenously determined once the fertilizer and groundnuts prices are known.

From 1964 to 1980, a credit system allowed the members of agricultural cooperatives to buy fertilizer and equipment at subsidized prices. The Senegalese government hoped that the subsidized inputs would compensate for the negative impact of low groundnut producer price. The marketing board was in charge of the delivery of the inputs. At the start of the marketing season, the farmers paid back the loans with groundnuts sales. The credit system was abolished in 1980 with the dissolution of the marketing board.

Rice is the major imported cereal and urban staple. An agency closely related to the marketing board (Caisse des perréquation et de stabilization de prix) has had a monopoly for this market. The retail price is fixed by law. It is usually set above the import cost, but the tariff has been moderate. The retail price has been subsidized when world prices increase unexpectedly. These increases in world prices have been transmitted to consumers over a period of time.

Senegal does not produce any wheat, and its import decisions are made by the marketing board. Wheat is milled and transformed into bread for consumption in urban areas. Prices are regulated by the government. Millers have been subsidized to sell the flour below cost to bakers. The retail price of bread is fixed by law at a very low level. In case of high cereal consumer prices, urban dwellers can create political agitation, weaken the legitimacy of the political decision maker, and vote against him. As in many developing countries, the threat of urban unrest is a strong deterrent against high food prices in Senegal (Bates, p. 33).

The Empirical Model

The indirect utility of the representative farmer, U_1, is

$$(10)\quad U_1 = U_1(P_m, P_{-m}, m_1(P_g, P_m, P_f, z_1) - C_1),$$

where P_m, P_{-m}, P_g, and P_f are the price of millet, price vector for consumption goods other than millet, producer price of groundnuts, and fertilizer, respectively. The variable z_1, a subset of z, expresses the influence of some of the exogenous variables on the restricted profit function (i.e., rural labor, land, and rainfall). The restricted profit function m_1 minus the cost of implementing conflict strategies, C_1, represents the farmer's net income.[3] At the cooperative solution, C_1 is equal to zero because conflict strategies are not used. By Hotelling's lemma, the supplies of groundnuts and millet, q_g^s and q_m^s, and the demand for fertilizer, q_f^d, are derived. The farmer markets his whole groundnut production. Roy's identity gives the farmer's demand for millet, q_m^d.

The farmer's payoff function is defined as the negative of the compensating variation for changes in prices and income,[4]

$$(11)\quad CV_1 = -[e_1(P_m, P_{-m}^0\, U_1^0,) - e_1(P_m^0, P_{-m}^0\, U_1^0) - m_1(P_g, P_m, P_f, z_1) + m_1^0\,(P_g^0, P_m^0, P_r^0, z_1)];$$

where m_1 and P_m refer to the current period, and m_1^0 and P_m^0 are their counterparts in the starting period, 1960; e_1 is the expenditure function of the farmer. Changes in the price P_{-m} are not considered, and compensating variation and millet demand are assumed to depend only on millet price and income. Millet supply and demand must be equal at the market equilibrium because millet is a nontraded commodity. Each farmer takes prices as given, but at the market level changes in the groundnuts and fertilizer prices affect the price of millet. Computation of the derivatives of the payoff functions with respect to price policies includes these general equilibrium effects.

A typical urban consumer has an indirect utility function U_2, with consumption prices and income as arguments:

$$(12)\quad U_2 = U_2(P_r, P_w, P[-r, -w], m_2 - C_2),$$

where P_r, P_w, $P[-r, -w]$ are the prices of rice, wheat products, and other goods, respectively. Income of the urban consumer is equal to the exogenous wage income m_2 minus the cost of applying conflict strategies C_2 (e.g., cost of rioting or striking). At the cooperative equilibrium, C_2 is equal to zero because of the absence of conflict. Roy's identity gives cereal demands q_r^d and q_w^d, which are assumed to be functions of rice and wheat consumer prices and of income. The urban consumer's payoff function is the

[3] The variable C_1 could be modified to include the cost of influencing the policy maker during the bargaining process (e.g., PAC contributions).

[4] Compensating variation, with equivalent variation, are standard measures of utility differences. They are money metric utility functions or compensation functions expressing the necessary dollar amount to offset a welfare change induced by changes in prices and income. They are linear in dollars and satisfy the axiom of linear invariance.

negative of the compensating variation for changes in P_w, P_r, and m_2:

$$(13) \quad CV_2 = -(e_2(P_r, P_w, P^0[-r, -w], U_2^0) - e_2(P_r^0, P_w^0, P^0[-r, -w], U_2^0) - m_2 + m_2^0),$$

with the superscript 0 denoting 1960 and e_2 representing the expenditure function of the urban consumer.

The marketing board chooses price variables P_g, P_f, P_r, and P_w to maximize the sum of net tax revenues in the four markets. This assumption is not very restrictive because the allocation of surplus generated through taxes is not specified. Under this assumption the marketing board can extract or transfer surplus depending on players' bargaining strength. The tax revenue function TR is

$$(14) \quad TR = (WP_g - P_g)q_g^s + (P_f - WP_f)q_f^d + (P_r - WP_r)q_r^d + (P_w - WP_w)q_w^d - D_1 - D_2,$$

where WP_g, WP_r, WP_w are the world prices of groundnuts, rice, and wheat, and WP_f is the ex-factory price of fertilizer. All these prices are exogenous; the world prices are multiplied by the nominal exchange rate and expressed in CFA francs. The nominal exchange rate (cost of dollars in CFA francs) is also exogenous. Variables D_1 and D_2 represent the cost to the marketing board of being in conflict with farmers and urban dwellers. The payoff function of the marketing board, CV_3, is the change in tax revenues when prices move from the starting to the current level,[5]

$$(15) \quad CV_3 = TR(P_g, P_f, P_r, P_w) - TR(P_g^0, P_f^0, P_r^0, P_w^0).$$

Equations (3) and (5) are applied to the Senegalese case. The strategies of the marketing board are the four price policies P_g, P_f, P_r, and P_w. Farmers and urban dwellers have political strategies that, although not observed, influence the marketing board in its pricing decisions. The optimum political pressure exerted by these two players on the policy maker satisfies conditior (5). Recall that farmers can smuggle their cash crop, default on loans, or withdraw their support to the existing political system; urban consumers can riot, go on strike, shirk, and vote against the elected policy maker.

The first-order conditions to maximize the welfare function W are

$$(16) \quad a(z)_1 \left(\frac{dCV_1}{dP_i}\right) + a(z)_3 \left(\frac{dCV_3}{dP_i}\right) = 0, \quad \text{for } i = g, f; \text{ and}$$

$$(17) \quad a(z)_2 \left(\frac{\partial CV_2}{\partial P_k}\right) + a(z)_3 \left(\frac{\partial CV_3}{\partial P_k}\right) = 0, \quad \text{for } k = r, w.$$

Total derivatives are taken in equation (16) to account for the intermarket relationships between millet, and groundnuts and fertilizer markets. Millet is a nontraded good whose market equilibrium is displaced by changes in policies P_g and P_f. The total derivatives dCV_j/dP_i in (16) are the sum of the direct effect, $\partial CV_j/\partial P_i$, and indirect effect via the millet price, $(\partial CV_j/\partial P_m)\cdot(dP_m/dP_i)$.

Before estimating (3), (16), and (17), we must specify the influence of z on the bargaining power coefficients. This step is necessary to recover the coefficients $a(z)_i$'s and their derivatives da_i/dz. The ratios of bargaining coefficients are approximated as linear functions of exogenous variables,

$$(18) \quad \frac{a_2(z)}{a_3(z)} = a_{23} + a_{231}WP_g, \text{ and}$$

$$(19) \quad \frac{a_3(z)}{a_1(z)} = a_{31} + a_{311}WP_r + a_{312}dol + a_{313}pop$$

where pop is the total population of Senegal, and dol is the exchange rate. Attempts to include the other exogenous variables of the model (land, rainfall, per capita income of the urban consumer, world price of wheat, and ex-factory price of fertilizer) into the ratios (a_i/a_j) proved unsuccessful.

The bargaining coefficients and their derivatives are recovered as follows. First, the bargaining coefficients are normalized to sum to one. The normalization, (18) and (19), are solved for the three coefficients,

$$(20) \quad a(z)_1 = \frac{1}{(1 + (1 + a_{23} + a_{231}WP_g)(a_{31} + a_{311}WP_r + a_{312}dol + a_{313}pop))},$$

[5] Other definitions of the utility function CV_3 were tried. When we assume an altruistic marketing board caring about both tax revenues and the income distribution between the urban and farm sectors, we obtain nonsensical results. We do not find evidence showing that the marketing board cares about the welfare of the other players outside of the bargaining process.

$$a(z)_2 = \frac{(a_{23} + a_{231}WP_g)(a_{31} + a_{311}WP_r + a_{312}dol + a_{313}pop)}{(1 + (1 + a_{23} + a_{231}WP_g)(a_{31} + a_{311}WP_r + a_{312}dol + a_{313}pop))}, \text{ and} \tag{21}$$

$$a(z)_3 = \frac{(a_{31} + a_{311}WP_r + a_{312}dol + a_{313}pop)}{(1 + (1 + a_{23} + a_{231}WP_g)(a_{31} + a_{311}WP_r + a_{312}dol + a_{313}pop)).} \tag{22}$$

Then the derivatives da_i/dz_k are computed taking into account that $\Sigma_{i=1}^{n} da_i/dz_k = 0$. Even if a specific exogenous variable enters only one equation, (18) or (19), it influences the whole bargaining-power structure via normalization of the a's. Equations (18) and (19) are substituted into (3), (16), and (17) to form the system

$$CV_3 = (a_{23} + a_{231}WP_g)(CV_2 + b_{23}), \tag{23}$$

$$CV_1 = (a_{31} + a_{311}WP_r + a_{312}dol + a_{313}pop)(CV_3 + b_{31}), \tag{24}$$

$$\frac{\partial CV_3}{\partial P_i} = -(a_{23} + a_{231}WP_g)\frac{\partial CV_2}{\partial P_i}, \text{ for } i = r, w; \text{ and} \tag{25}$$

$$\frac{dCV_1}{dp_k} = -(a_{31} + a_{311}WP_r + a_{312}dol + a_{313}pop)\frac{dCV_3}{dp_k}, \text{ for } k = g, f. \tag{26}$$

Equations (23)–(26) are estimated with time-series data from 1960 to 1980. The estimation is organized in two steps. First, supply and demand equations are estimated to generate measurements of the payoff functions and their derivatives. Then the game is estimated.

Assuming millet expenditure is linear in millet price and farm income, the estimated millet demand yields the parameters necessary to compute the farmer's compensating variation. The estimated groundnut and millet supplies are linear in relative prices, P_g/P_f and P_m/P_f, and give the profit function's parameters needed to compute the derivatives of the farmer's compensating variation and tax-revenue function with respect to P_g and P_f.

No simple well-behaved functional form could fit the urban consumption data. The sum of changes in consumer surplus in the rice and wheat markets and changes in income approximates the urban consumer's compensating variation. A double logarithmic specification expresses cereal urban demands as functions of the two cereal prices, income and time trend. The estimated urban consumption parameters are used to compute the derivatives of the urban consumer's and marketing board's payoff functions with respect to P_r and P_w. This first step of the estimation and the data are reported in an appendix, available upon request from the author.

Because the payoff functions and their derivatives are endogenous variables, an instrumental variable technique is required. The payoff functions and their derivatives are the equilibrium outcome of the game; hence, they are simultaneously determined. Thus, iterative two-stage least squares is used. The parameter estimates are shown in table 1, with the bargaining-power coefficients implied by these estimates. At the sample mean the bargaining coefficient estimates are $a_1 = .5906$, $a_2 = .1351$, $a_3 = .2743$, respectively, for the farmer, urban consumer, and marketing board. The larger magnitude of a_1 is unexpected because of the price policies favoring urban consumers and the marketing board. It is explained as follows. Farmers' reference point is closer to their optimum payoff than are those of the urban consumers and the marketing board. In case of conflict, farmers have their subsistence crop as an alternative; conversely, the marketing board and urban consumers have more to lose in a disagreement. They will be much worse off because their reference points are further away from the optimum solution and this weakens their bargaining strength (Thomson 1987).[6]

The derivatives of the coefficients a_i's with respect to the four exogenous variables are calculated at the mean with the regression estimates and are also reported in table 1. The farmers and the marketing board enhance their bargaining positions with a higher world price of groundnuts. More expensive rice imports disadvantage urban consumers and the marketing board relative to the farmers. Less intuitive directions are obtained for the other two exoge-

[6] Possible misspecification of the payoff functions of the players could also bias the a's estimates.

nous variables. Population and exchange rate influence positively the bargaining position of urban consumers and the marketing board to the disadvantage of farmers.

With estimates of da/dz, $\partial CV_i/\partial s'$, $\partial^2 CV_i/\partial s'\partial s$, and $\partial^2 CV_i/\partial s'\partial z_j$, the multipliers, ds_k/dz_j, are computed as in (8). Seven possible shocks are considered: changes in the world price of groundnuts, wheat, and rice, WP_g, WP_w, WP_r; in the exchange rate, dol; in the ex-factory price of fertilizer, WP_f; in population, pop; and in the income of urban consumers, m_2. The multipliers ds/dz_j are presented in table 2 in elasticity form $(ds/s/dz_j/z_j)$. The groundnut producer price is negatively related to most variables except the world price of groundnuts. The fertilizer prc ducer price decreases with higher world price of groundnuts and rice and increases with risin population, exchange rate, and ex-factory pric of fertilizer. The rice consumer price is nega tively influenced by a rise in world cereal price and urban income. Opposite effects are obtaine for the world price of groundnuts, populatior and exchange rate. Higher urban income, por ulation, and world price of rice induce increase in the wheat consumer price; in contrast, ir creases in exchange rate, world prices of whea and groundnuts lower the same consumer price

Estimation of Behavioral Equations

Behavioral equations are also estimated with th time-series data included in the appendix. Th behavioral equations are specified linearly, as i (9), with the shocks considered in the previou section as explanatory variables. This allow comparison of the two approaches for the sam set of exogenous shocks. The equations are

$$(27)\quad P_i = \beta_{i0} + \beta_{i1}WP_g + \beta_{i2}WP_r + \beta_{i3}pop + \beta_{i4}dol + \beta_{i5}WP_f, \text{ for } i = g, f; \text{ an}$$

$$(28)\quad P_k = \beta_{k0} + \beta_{k1}WP_g + \beta_{k2}WP_r + \beta_{k3}pop + \beta_{k4}dol + \beta_{k5}m_2 + \beta_{k6}WP_w, \text{ for } k = r, w$$

Assuming additive error terms that satisfy th Gauss-Markov assumptions, (27) and (28) ar estimated with ordinary least squares, and th results are presented in table 3. Overall, th regressions give good fit (high R^2), although som variables are not statistically significant (low T value). The multipliers ds/dz based on regres sions are presented in elasticity form in table 4

The two approaches give the same impact d rections in more than 75% of the cases, but th magnitudes differ. The game approach tends t

Table 2. Impact of Exogenous Shocks on Price Policies

yield larger multipliers. Contradictory results occur for the impacts of the world price of rice on the groundnuts and rice price policies, the influence of the population variable, and exchange rate on the fertilizer price, and the effect of urban income on the rice consumer price.

The game-theoretic approach yields comparative statistical results without considering lags in adjustment of policies to exogenous shocks and in responses of economic agents to policy changes. The introduction of lagged values of z (except population), as additional explanatory variables in (27) and (28), reduces the difference in magnitudes between the two approaches. The results are shown in table 5. Unfortunately, the small size of the data set limits

the number of variables and lag structures that could be incorporated into (27) and (28), and decreases the statistical significance of the estimated regressions. Nevertheless, the contrast between the game theory and reduced-form results is consistent with a long-run/short-run dichotomy. The actual data reflect the dynamics of players' responses, whereas the game approach assumes instantaneous adjustments. The linear specification of the behavioral equations might be another source of discrepancies between the two sets of results. The introduction of higher-order terms would be preferable if sufficient data were available.

Finally, the multipliers derived from the game approach are conditional to the specification chosen for the players' preferences and technology. Potential misspecification of the utility or profit functions could bias the multipliers and explain contradictory results between the two methods.

Concluding Comments

The game-theoretic framework predicted the response of the endogenous public policies to a changing environment. Derivation and quantification of the impact of exogenous shifters on the game equilibrium allowed an estimate of policy responses to those shocks. This approach also provided for the policy behavioral equations, a specification consistent with the bargaining process underlying the policies.

The political economy of food and agricultural prices in Senegal illustrated the proposed approach. The effect of shocks on the price policies was estimated with the bargaining game model and with the behavioral equations. The former computation resulted in larger multipliers than the latter. The Senegalese application therefore suggests that reduced-form multipliers describe short-term responses and raises the issue of appropriate lag structure to capture full adjustment.

As Abbott (1979b) argued, the structural model and reduced-form approach give complementary insights on policies' endogeneity. The behavioral equation approach avoids specification and estimation of players' taste and/or technology parameters; but it offers no insight on the structure of policy decisions, and the linear specification limits the validity of predictions to small shocks. An ad hoc specification can be used if some structural characteristics are known; but the behavioral equation will not correspond to a given structural model, and its coefficien will be difficult to interpret. If short-term pr diction is the main motivation, such ad hc models are appropriate.

The bargaining game framework incorporat agents' behavior and reactions into the polic process. Estimated bargaining weights reveal tl welfare trade-offs made by policy makers in the policy choices. Assumptions about players' b havior, technology, and preferences are nece sary to quantify the game and the policy r sponses to shocks; adding more a priori structu could possibly bias the analysis. This approac also requires a well-documented understandin of the political economy and institutions i volved in policy decisions. As the empirical r sults suggest, game-policy multipliers abstra from the dynamics of adjustment and constitu long-term responses to shocks.

Some Neglected Social Costs of Government Spending in Farm Programs

Julian M. Alston and Brian H. Hurd

Economic welfare analyses of farm programs typically assume that the direct social opportunity cost of subsidy payments is one dollar per dollar of government spending. Recent literature suggests that the marginal opportunity cost of a dollar of U.S. federal government spending is more likely to be in the range of $1.20 to $1.50. This implies that the net social costs of farm programs that involve government spending are significantly greater than the typical estimates. In addition, the normative efficiency ranking of alternative policies is sensitive to the marginal opportunity cost of government spending.

Key words: deadweight cost of taxes, efficiency of transfers, farm programs.

The economic welfare consequences of U.S. farm programs have been analyzed and measured in a great many studies.[1] Almost all such studies assume that the social opportunity cost of a dollar of government spending is one dollar, and the net social cost of government spending is measured entirely as the indirect cost of the Harberger triangles of distortions in commodity markets induced by the programs. Such an approach does not consider the welfare costs of distortions caused by the collection of taxes elsewhere in the economy to finance government spending in farm programs.

That the opportunity cost of a dollar of government spending is not one dollar is generally well known to economists, certainly among those familiar with the literature on public economics (e.g., Atkinson and Stiglitz, Stiglitz, Harberger) and optimal taxation (e.g., Mirrlees, Sandmo). While the profession has not reached total agreement on the magnitude of this cost, various studies support the view that the margin excess burden of taxation in the United Stat is significant, likely to fall between 20% ai 50%.[2] Thus, the marginal social welfare cost a dollar of government spending (*MWC*) is like to be between $1.20 and $1.50. The implic tions for the social costs and efficiency rankii of farm programs are direct and profound.[3]

In this paper we focus on the implications f the choice of policy instrument. The exact ma nitude of *MWC* is not crucial to the argumer We present a simple diagrammatic, comparati

Special thanks go to Bruce Gardner and an anonymous referee whose comments led to significant improvements in the analysis. Any remaining errors are the authors' responsibility.

[1] Two recent examples are Gardner (1987b) and Council of Economic Advisers. Two early examples are Johnson and Wallace. Most issues of this *Journal* contain at least one instance, as do similar publications.

[2] The literature contains some very wide ranges of estimates, l most studies report a narrower range of preferred estimates. I example, Browning (1987, p. 74) summarized his point of vi as: "The estimates of marginal welfare cost developed here rar from just under 10 percent to just over 300 percent. Extreme (l not impossible) combinations of assumptions about contribut factors are required to generate these polar estimates. My prefer estimates lie in the range of 20 to 50 percent. Several other rec studies have also developed estimates that lie approximately in t range." The other recent studies include, for example, Balla Shoven, and Whalley, who state (p. 128) that "the welfare l from a 1 percent increase in all distortionary taxes is in the rar of 17 to 56 cents per dollar of extra revenue, when we use elastic estimates that we consider to be plausible." See also Browning (19 1987), Stuart, and Findlay and Jones who suggest a range of 2 to 65% for Australia.

[3] For instance, Gardner (1987b) estimated that taxpayer costs farm programs were $17.7 billion for 1987, and his estimates yi a net social cost (corresponding to Harberger triangles of resou distortions in commodity markets) of $6.0 billion per year (see a Council of Economic Advisers). Adjusting these estimates for *MV* of, say, 20% to 50%, the full taxpayer costs are $21.2 billion $26.6 billion in 1987. The corresponding net social costs are $ billion to 14.9 billion, between 50% and 150% greater than conventional estimates. Because the marginal welfare costs are u certain, these estimates are conjectural.

static analysis of the effects of the excess burden of taxation on the normative efficiency ranking of a range of alternative policy instruments. The analysis, which draws heavily on Gardner (1983, 1987a, c) for concepts and its approach, is concerned with efficient redistribution to farmers in terms of minimizing the total costs to consumers and taxpayers of achieving a given increase in producer surplus. This is equivalent to minimizing the excess burden of achieving a given net benefit to farmers from farm programs. The analysis begins with the case of a closed economy and considers the relative efficiency of production controls and output subsidies. Then, policies for traded goods in a small open economy are considered.

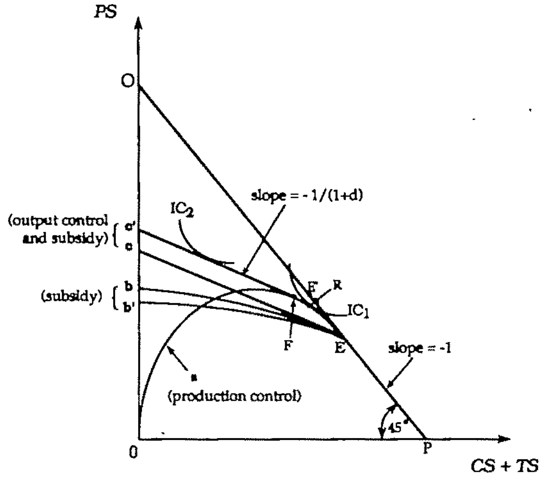

Figure 1. Efficient redistribution using production controls and output subsidies in a closed economy

Efficient Commodity Policies for a Closed Economy

Gardner (1983, 1987c) shows how the excess burden of general taxation may influence the relative efficiency of production controls and subsidies, treating the alternatives as mutually exclusive. Here we show the effects when the policies are not mutually exclusive and may be combined efficiently. Consider the simple case of a nontraded commodity when policies can involve welfare losses from distortions in both the commodity market and elsewhere in the economy (through taxes to finance farm programs). The surplus transformation curves (*STC*) in figure 1 show the trade-offs between producer surplus (*PS*) and the sum of consumer surplus (*CS*) and taxpayer surplus (*TS*) for a range of policies under various assumptions.[4] The shapes of these curves are defined by the parameters of supply and demand and the opportunity cost of government spending. The competitive equilibrium is *E*.

First, consider the case where there is no excess burden of taxes to finance subsidies in this market. A production control alone would allow transformations along (*a*); an output subsidy alone would allow transformations along (*b*) which is arbitrarily assumed to lie below (*a*) initially but to cross it eventually. Both (*a*) and (*b*) are concave, reflecting the increasing deadweight cost relative to farmer benefits as transfers away from consumers/taxpayers increase. In the case of production controls, marginal producer benefits are diminishing and eventually become negative (i.e., when quota is reduced below the monopoly maximum profit point). In the case of production subsidies, marginal producer benefits are diminishing but positive throughout.

Here, an exclusive (all-or-nothing) choice between production controls and subsidies might favor either policy, and multiple equilibria are possible, depending upon the shape of the government's indifference curves between producer surplus and consumer cum taxpayer surplus. Assume that the production control is preferred as indicated by the tangency with the indifference curve (IC_1) at point *R*. This solution is clearly inferior to point *E'*, which may be achieved by combining a subsidy with a production control holding output at the competitive quantity (Q_e). Therefore, when the opportunity cost is one dollar per dollar of government spending, it is always inefficient to specialize in either a subsidy or a production control. The most efficient option here would be to restrict output to Q_e using a quota and use a subsidy to achieve the desired transfer. Any transfer along the 45° line *OP* can be achieved in this way without any distortion in resource use, as the equivalent of a lump-sum transfer. That is, the efficient *STC* for this problem is the line *OP*.

Suppose, instead, that a dollar of subsidy program payments reduces taxpayer surplus by more than one dollar. Specifically, assume that the marginal deadweight cost of raising a dollar for

[4] Gardner (1983, 1987a) used a similar diagram; but, instead of the sum of consumer surplus and taxpayer surplus ($CS + TS$) he had, equivalently, consumer surplus less taxpayer cost ($CS - T$). The former is preferred here because it makes clearer that we are considering implications for welfare of taxpayers as distinct from the budget costs of programs.

subsidy payments is constant at d, so that a dollar of subsidy costs $(1 + d)$ dollars of taxpayer surplus. The *STC* for a subsidy alone is therefore lower at (b'). This increases the chance that an all-or-nothing choice between production controls and subsidies will favor production controls. Consider, instead, a subsidy with output fixed at the competitive quantity (Q_e), as in the previous case. The surplus transformation curve for this policy is the straight line (c) with a slope $-1/(1 + d)$. This line (c) is also the *STC* for a decoupled lump-sum transfer, which is clearly not the most efficient policy in this case. A superior option would be to combine a subsidy with a production control at the quantity corresponding to point F, where the marginal rate of surplus transformation (i.e., the slope of the *STC*, $dPS/d[CS + TS]$) for production controls equals $-1/(1 + d)$, and the marginal deadweight cost from further reductions in quantity equals the marginal deadweight cost of taxation. This option is shown by (c'), which is parallel to (c) but above it. Thus, the curve EFc' shows the efficient *STC* for this problem. In this case it may be efficient to specialize in production controls or to use a mix of policies. For example, if political preferences correspond to IC_1 a production control alone is superior. If preferences correspond to IC_2, a mix is superior, but it is never efficient to use a decoupled lump-sum transfer in this case.

Figure 2 shows, in a more familiar supply and demand setting, the efficient combination of output controls and subsidies taking account of deadweight costs of taxation. In figure 2, Q_e is the competitive output and Q_f is the optimum output quota corresponding to point F in figure

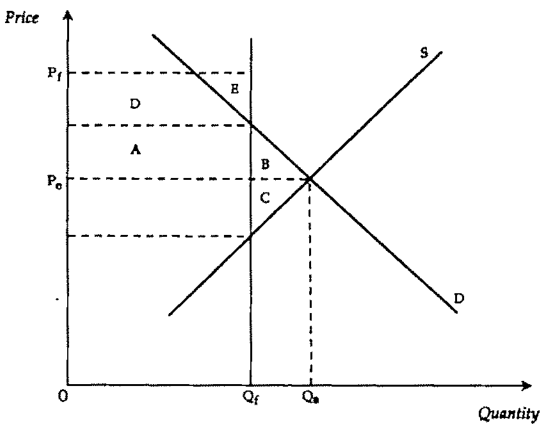

Figure 2. Effects of combining an output control and subsidy in a closed economy

1. Restricting production to Q_f yields a net pr ducer benefit equal to area $A - C$ with a co responding social cost equal to triangle $B + ($ At this point the marginal deadweight cost (raising producer benefits by the quota alone d (that is, a deadweight loss triangle $B + C$ wi increase by d cents when quota is reduced su ficiently to yield an additional dollar of pr ducer benefits in area $A - C$). For transfers producers less than $A - C$, it is efficient to u: a quota alone. For transfers greater than $A - ($ it is efficient to use a subsidy in combinatic with the quota at Q_f. In figure 2, producers r ceive a total net transfer equal to area $(A - ($ $+ (D + E)$, of which $D + E$ is in the form (output subsidy; the cost to consumers is area $+ B$; the taxpayer cost is area $(1 + d)(D + E$ the net social cost is equal to $d(D + E) + (B$ $C)$. This is the minimum social cost of achie ing that transfer given the policy options co sidered.

Efficient Commodity Policies for a Small Open Economy

Figure 3 represents a commodity market for small country importer with domestic supply (: and demand (D) and an import supply curv which is perfectly elastic at P_0. We will con pare a range of policies which confer an equi alent gain to producers equal to area $(A + B$ These are (a) a tariff of T per unit (equivale to an import quota of N with government r taining quota rents), (b) an output subsidy of per unit, (c) a production quota of Q_0 with a output subsidy of $(A + B)/Q_0$ per unit, and (a tariff of T per unit (or an import quota of $+ M)$ combined with a production quota of $($

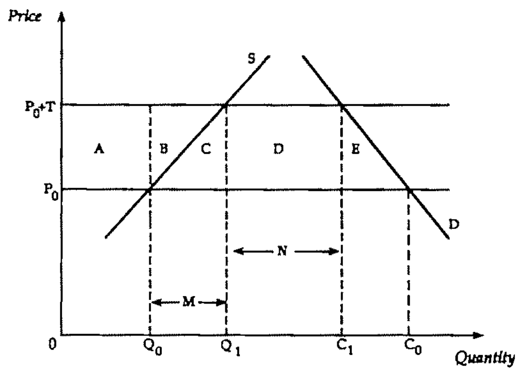

Figure 3. Efficient redistribution for a smal country importer

and a subsidy of B/Q_0 per unit. The upper half of table 1 summarizes the surplus distribution effects and deadweight losses from these alternative policies. The net column shows the deadweight losses required to achieve the transfer to producers. The most efficient policy is the one with the smallest deadweight loss.

The upper half of table 2 represents these deadweight losses algebraically in terms of elasticities of supply and demand and so on. To derive these expressions, the supply and demand curves were approximated linearly in terms of the following parameters valued at the competitive equilibrium: supply elasticity (ϵ), absolute value of demand elasticity ($\eta > 0$), percentage import tariff ($\tau = T/P_0$), and domestic production as a share of consumption ($k_d = Q_0/C_0$). To compare policies, the net social costs of each are expressed relative to those of the output subsidy. Then, to simplify the expressions, the net social costs for each policy (relative to the output subsidy) are expressed per dollar of con-

Table 1. Consumer, Taxpayer, and Net Social Costs of Surplus Redistribution Policies for a Small Open Economy

Policy	Consumer Cost	Taxpayer Cost	Net Social Cost
Importable			
Tariff (T)	$(A + B + C + D + E)$	$-(1 + d)D$	$(C + E) - dD$
Output subsidy (T)	0	$(1 + d)(A + B + C)$	$C + d(A + B + C)$
Quota (Q_0) plus subsidy $[(A + B)/Q_0]$	0	$(1 + d)(A + B)$	$d(A + B)$
Tariff (T), quota (Q_0) and subsidy (B/Q_0)	$(A + B + C + D + E)$	$-(1 + d)(D + C)$	$E - d(D + C)$
Exportable			
Output subsidy (R)	0	$(1 + d)(G + H + I + J + K)$	$K + d(G + H + I + J + K)$
Export subsidy (R)	$(G + H + I)$	$(1 + d)(I + J + K)$	$(I + K) + d(I + J + K)$
Quota (Q_0) plus subsidy of $(G + H + I + J)/Q_0$	0	$(1 + d)(G + H + I + J)$	$d(G + H + I + J)$
Price pooling scheme subsidy (R), Tax (W)	$(L + F + G + H + I)$	0	$(F + H + I + K)$

Notes: The entries in this table under importables correspond to the areas of surplus changes in figure 3 associated with an increase of producer surplus of area $(A + B)$. The entries under exportables correspond to a producer surplus change of $(G + H + I + J)$ in figure 4. The capital letters refer to areas in the figures, and lower case 'd' represents the marginal deadweight cost per dollar of government spending. The net social cost is equal to the consumer cost plus the taxpayer cost minus the benefit to producers.

Table 2. Efficiency Ranking of Surplus Redistribution Policies in a Small Open Economy

	Net Social Cost Relative to Output Subsidy	
Policy	Geometric Area	Algebraic Measure
Importable		
Quota (Q_0) plus subsidy $[(A + B)/Q_0]$	$-(1 + d)C$	$-(1 + d)\cdot\frac{1}{2}\cdot\tau^2\epsilon k_d$
Tariff (T)	$E - d(A + B + C + D)$	$\frac{1}{2}\cdot\tau^2\eta - d\tau(1 - \tau\eta)$
Tariff (T), quota (Q_0) and subsidy (B/Q_0)	$E - d(A + B + C + D) - (1 + d)C$	$\frac{1}{2}\cdot\tau^2[\eta - (1 + d)k_d\epsilon] - d\tau(1 - \tau\eta)$
Exportable		
Quota (Q_0) plus subsidy of $(G + H + I + J)/Q_0$	$-(1 + d)K$	$-(1 + d)\cdot\frac{1}{2}\cdot\rho^2\epsilon$
Export subsidy (R)	$I - d(G + H)$	$\frac{1}{2}\cdot\rho^2\eta c_d - d\rho(1 - \rho\eta)c_d$
Price pooling scheme: output subsidy (R) with consumption tax ($R + W$)	$(F + H + I) - d(G + H + I + J + K)$	$\frac{1}{2}\cdot c_d\gamma^2\eta - d\rho(1 + \rho\epsilon)$

Notes: The geometric areas are derived from those in table 1 by subtracting the net social cost of the output subsidy from that of the output subsidy. The parameters are supply elasticity (ϵ), demand elasticity ($\eta > 0$), import tariff rate (τ), domestic production as a share of consumption (k_d), export subsidy rate (ρ), domestic consumption as a share of production of the exportable (c_d), and the domestic consumption tax rate (γ) necessary to finance an output subsidy of ρ percent. The equations are defined per dollar of total consumption expenditure for the importable and per dollar of total revenue for the exportable. See the text for further details.

sumer expenditure in competitive equilibrium. A positive expression indicates the policy involves a greater net social cost than an equivalent output subsidy.

Considering individual policies in isolation with $d = 0$, an output subsidy is clearly superior to a tariff (or equivalent import quota) as a means of transferring income efficiently to producers. A production quota alone is useless in this setting. However, an output quota combined with a subsidy is equivalent to a lump sum transfer and more efficient than any single instrument. A tariff combined with a quota and a subsidy might be more efficient than an output subsidy (i.e., area $C >$ area E) depending on the relative slopes of supply and demand. These rankings may change completely when $d > 0$. Indeed, it is possible that the tariff policies that raise government revenues could raise the sum of taxpayer and consumer surplus while increasing producer surplus. Certainly some tariff will be superior to free trade when d is positive, even in this small country case. The combined quota and output subsidy policy remains unambiguously superior to the output subsidy alone, and the combined tariff, production quota, and subsidy remains superior to the tariff alone. However, it is not possible to rank all the policies unambiguously in general from theory alone. As shown in table 2, the ranking will depend on the sizes of the transfer, elasticities of supply an demand, the fraction traded, and the margin value of government revenue (d).

We do not formally analyze the large countr case, which is complicated because large cour try importers are always capable of improvin upon free trade by monopsonistic use of mark power. However, by analogy with the sma country results, the ranking of policies will b ambiguous. For large values of d, a tariff (pe haps in conjunction with output controls) is likel to be favored strongly over an output subsidy a means of redistributing surplus toward prc ducers.

The case of a small country exporter is show in figure 4. The curves are domestic demand (D supply (S) and export demand which is perfectl elastic at P_0. The free market equilibrium outpu is Q_0. Here we compare four policies which re sult in equivalent gains to producers equal to are ($G + H + I + J$). These are (a) an output sub sidy (R per unit), (b) an export subsidy (R pe unit), (c) an output control fixing output at Q plus an output subsidy of $(G + H + I + J)/Q$ per unit, and (d) a revenue pooling price di crimination scheme (of the type used widely i Australia and Canada) which is equivalent to a export subsidy (R per unit) financed entirely b a domestic consumption tax (W per unit).

The lower half of table 1 summarizes the su

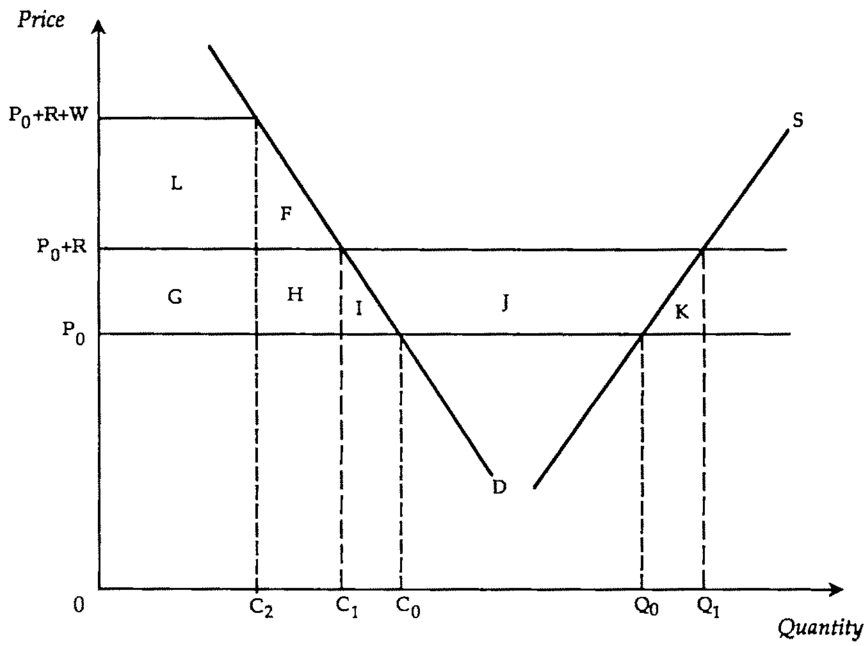

Figure 4. Efficient redistribution for a small-country exporter

plus distribution effects and deadweight losses from these alternative policies, and the lower half of table 2 represents the deadweight losses algebraically. To derive the formulas, the supply and demand curves were approximated linearly in terms of the following parameters valued at the competitive equilibrium: supply elasticity (ϵ), absolute value of demand elasticity ($\eta > 0$), percentage export subsidy ($\rho = R/P_0$), domestic consumption as a share of production of the exportable ($c_d = C_0/Q_0$), and the percentage domestic consumption tax [$\gamma = (R + W)/P_0$] necessary to finance an output subsidy of ρ percent. The net social costs of each policy are expressed relative to those of the output subsidy, scaled per dollar of producer revenue in competitive equilibrium.

Under the usual assumption ($d = 0$), a production control with an output subsidy would be the most efficient means of transferring income to producers, equivalent to a lump-sum transfer; the next most efficient policy would be a subsidy alone; third would be a subsidy on exports only; least efficient of all would be the producer price pooling scheme. These policy rankings may change when we allow $d > 0$. The quota plus subsidy option remains superior to the subsidy on all output. However, other policies may be more efficient than both of these options. The answer depends on the relative magnitudes of the marginal taxpayer costs of government spending and the marginal deadweight losses from distortions in consumption and production. In turn, these will depend on the elasticities of supply and demand, the domestic market share, and the size of the transfer to producers. For large values of d, an export subsidy could be more efficient than a subsidy on all output and a producer price pooling scheme could be most efficient.

We do not formally analyze the case of a large country exporter, which (like the case of the large country importer) is made more complicated because free trade will not maximize total domestic surplus, even when $d = 0$. When $d = 0$, the most efficient policy would be to price discriminate between domestic and export markets and transfer income to producers in a lump sum fashion through a combination of output control and subsidy. For large values of d, production controls may be the most efficient means of transferring income to producers while exploiting market power in export markets and avoiding any excess burden of government expenditure.

General Implications and Limitations of the Analysis

Our main results are three. First, the net social costs of farm programs that involve subsidies are greater, perhaps by orders of magnitude, than typical estimates suggest. Second, when the marginal welfare cost of government spending (*MWC*) is zero, it is always inefficient to specialize in single instrument policies (supply controls or subsidies); this result does not hold when *MWC* is not zero. Third, the normative efficiency ranking of alternative policies is sensitive to *MWC* (in conjunction with other factors).

The analysis has focused mainly on this third point. In the absence of deadweight costs of taxpayer surplus foregone to finance government spending, it is possible to rank the alternative policies unambiguously in terms of their relative efficiency at transferring income to producers.[5] Also, in such circumstances, it is always possible to devise a combination of commodity policies that is equivalent to a lump sum transfer to producers. However, once allowance is made for deadweight costs of taxpayer surplus, it is no longer possible to rank policies unambiguously from theory alone nor to make the equivalent of lump sum transfers. There is always a deadweight burden of either consumer surplus or taxpayer surplus, or both, and the ranking of policies is an empirical matter.

We have shown (see table 2) how the ranking of policies for traded goods may vary with changes in elasticities of supply and demand, the size of the transfer to producers (i.e., the size of the producer subsidy equivalent), the marginal opportunity cost of government spending and, for traded goods, the fraction of consumption or production traded. However, we have neglected some other factors that may influence the ranking. In particular, real-world supply controls are rarely as efficient or benign as the analysis would suggest. Output quotas are rarely freely transferable, which is a requirement for costs to be minimized. Often, the costs of limits upon quota transferability are found to be much greater than the Harberger triangles of resource distortions associated with quotas (e.g.,

[5] The information requirements to do this ranking depend upon the options being considered. When $d = 0$, for instance, in the cases analyzed in the text, there are no requirements for information about market parameters; but to compare mutually exclusive output quotas and output subsidies requires measures of elasticities of supply and demand and the magnitude of the transfer (e.g., see Gardner 1983, 1987a, c).

Lermer and Stanbury). When input controls are used as a surrogate for output controls, there are costs of distortions in input combinations to be considered (e.g., Johnson). In addition, there are administrative costs of policies and costs of rent-seeking which are likely to vary between instruments and among commodities.

Conclusion

Decisions about farm programs involve choices among policy instruments of the types considered in this paper. Typically the alternatives are analyzed by treating government spending as a transfer payment which amounts to an assumption that a dollar of government spending involves a net social cost of one dollar. This leads to a bias in the analysis in favor of policies that involve government spending relative to alternatives that do not. The growth of expenditures on U.S. farm programs during the early 1980s reflects, in part, an emphasis on the use of budgetary measures rather than regulatory alternatives to raise farm returns. In the 1985 farm bill, output subsidy policies were retained in preference to output controls, which were proposed as an alternative. This outcome may have pleased some economists who have argued for budgetary (rather than regulatory) measures because they are more transparent; but transparency did not prevent program payments reaching an all-time high of almost $26 billion in 1986.[6] The benefits of transparency may have been overstated; the costs have almost certainly been understated.

Currently it is fashionable to argue for "decoupling" farm programs in the sense that income transfers should be achieved with minimal consequences for commodity markets. Along with the benefits from transparency, the benefits from decoupling may be illusory. The issue here is whether the costs of distortions in commodity markets are necessarily greater than the costs of distortions introduced elsewhere in the economy to finance "decoupled" transfers. As with the choice between alternative commodity policy instruments, the choice between a commodity policy and a decoupled income transfer policy depends upon the answers to empirical questions which will vary among commodities.

The issue of the full taxpayer costs of government subsidies has received too little atte tion in the welfare analysis of farm program Usually the deadweight costs of taxes to rai government revenues to fund farm programs a assumed away or ignored. Occasionally the i sue is raised, but it is rarely given more weig than as a qualification to the main results. O exception is Gardner (1983). In empirical wor apart from some examples in the area of me suring returns to research (e.g., Fox), in gener a dollar of government spending in farm pr grams is assumed to cost society a dollar. O results indicate that the deadweight costs of tax elsewhere in the economy are too important be ignored in analyzing farm programs.

[6] This is not to say that transparency had no effect. It may be that less transparent policies would have involved greater implicit transfers to farmers.

Revenue-Neutral Tax Policies Under Price Uncertainty

Garth J. Holloway

The firm's response to revenue-neutral taxation is investigated under price uncertainty. Revenue-neutral policies adjust simultaneously the marginal tax rate and the level of exemptions while keeping expected tax receipts constant. Nonincreasing absolute risk aversion is sufficient to sign the firm's response: a reduction in the marginal rate causes the firm to contract output. Implications are established for the equilibrium level of treasury receipts.

Key words: price uncertainty, risk aversion, tax policy.

Several authors have recently investigated the competitive firm's response to a change in the marginal tax rate when the product price is random. This response depends on the decision maker's absolute and relative risk aversion (Katz) or, equivalently, on the less familiar concept of partial relative risk aversion (Briys and Eeckhoudt). The results show that, in general, it is not possible to sign the firm's response by assuming that absolute risk aversion is nonincreasing in wealth.

The principal purpose here is to determine the firm's response to a revenue-neutral change in the tax rate. Such a policy adjusts simultaneously the marginal rate and the level of exemptions while keeping total tax receipts constant. The 1986 Tax Reform Act is an example of such a policy in which marginal tax rates were lowered (Hanson and Bertelsen, p. 1014; Lins, Offutt, and Richardson, p. 1022). It is shown that nonincreasing absolute risk aversion is sufficient to sign the firm's response and that a reduction in the marginal rate causes the firm to contract output. The intuition behind this result is given below, following the development of a simple model of supply response under price uncertainty. Conditions are given under whic[h] the equilibrium level of tax receipts is likely t[o] rise.

The Model and Results

Consider a competitive firm producing output x, facing random price, p, and operating wit[h] cost structure $C(x) = c(x) + f$, such that $c(0) =$ 0 and $c'(x) > 0$. When faced with a tax schem[e] comprised of profits that are exempt from tax ation, $Y \in [0, px - C(x)]$, and a constant mar ginal tax rate, $\tau \in (0, 1)$,[1] the firm solves

$$(1) \quad \max_x: E\{U(W_o + [px - c(x) - f][1 - \tau] + Y\tau)\}$$

where E is the expectations operator defined ove[r] p; U denotes risk-averse preferences such tha[t] $U' > 0$, $U'' < 0$, and $R_a(W) \equiv -U''(W)/U'(W[)]$ is nonincreasing in W; and $W = W_o + \Pi(x)$ where W_o is initial wealth and $\Pi(x)$ is profit.

Necessary and sufficient conditions for [a] maximum, after factoring out the nonzero con stant, $[1 - \tau]$, are, respectively,

$$(2) \qquad E\{U'(W)[p - c'(x)]\} = 0,$$

$$(3) \qquad E\{U''(W)[p - c'(x)]^2[1 - \tau] - U'(W)c''(x)\} \equiv \phi(x; Y, \tau) < 0.$$

Assume that $\tilde{x}$ is the nonzero, finite, and uniqu[e] solution to (2) and that (3) is satisfied. Onc[e] product price p is realized, an industry com

Garth J. Holloway is a graduate research assistant, Department of Agricultural Economics, Purdue University.

The author is grateful to Paul Preckel for providing motivation to write this note. Valuable comments from Rulon Pope are also appreciated. The author is solely responsible for any remaining errors.

[1] A flat rate of tax above an exemption is perhaps the simple[st] form of a progressive tax and is commonly referred to as a d[e]gressive tax (see, e.g., Browning, p. 288).

prised of n such firms makes tax payments to the treasury in the amount,

$$(4) \qquad \tilde{G} = n\tilde{g} = n[p\bar{x} - c(\bar{x}) - f - Y]\tau.$$

When price is random, the fiscal authority chooses the levels of Y and τ with incomplete information about p. A revenue-neutral tax policy consists of combinations of Y and τ that keep the expected level of fiscal receipts constant. Taking expectations and totally differentiating in (4), the policy satisfies

$$(5) \qquad \left.\frac{\partial Y}{\partial \tau}\right|_{dE\{\tilde{G}\}=0} = \frac{\mu_p \bar{x} - c(\bar{x}) - f - Y}{\tau},$$

where $\mu_p = E\{p\}$.

To determine the effect on output of policies defined by (5), implicitly differentiate in the first-order condition, (2), and evaluate the resulting expression at $x = \bar{x}$. This yields a Slutsky equation of the form,[2]

$$(6) \qquad \left.\frac{\partial x}{\partial \tau}\right|_{dE\{\tilde{G}\}=0} = \frac{\partial x}{\partial \tau} + \frac{\partial x}{\partial Y} \cdot \left.\frac{\partial Y}{\partial \tau}\right|_{dE\{\tilde{G}\}=0.}$$

The first term on the right-hand side is the direct effect on output of a change in τ; the second term is the indirect effect induced by the change in Y that results from constraining the expected level of receipts in accordance with (5). This reduces to

$$(7) \qquad \left.\frac{\partial x}{\partial \tau}\right|_{dE\{\tilde{G}\}=0} = \frac{\bar{x}}{\phi} E\{[U''(\tilde{W})[p - c'(\bar{x})][p - \mu_p]\},$$

which is strictly positive under nonincreasing aboslute risk aversion (Ishii). Thus, a revenue-neutral reduction in the marginal tax rate causes the firm to contract output.

In the general case investigated by Katz and by Briys and Eeckhoudt, a *ceteris paribus* reduction in the tax rate increases both the mean and variance in the firm's profits, which causes conflicting impacts on the firm's output. Under revenue neutrality a decline in the marginal rate increases the variance in profits but leaves the mean unchanged. It is well known that a risk-averse firm will contract output in response to a marginal increase in uncertainty (Ishii), and thus the sign in (7) is positive.

It is easy to establish that the variance in profits and the variance in tax payments move in opposite directions as a result of the tax change because

$$(8) \qquad \frac{\partial \text{var}(\Pi)}{\partial \tau} = \frac{\partial \text{var}(g)}{\partial \tau} \cdot [(\tau - 1)/\tau].$$

This yields an additional interpretation of the policy: a revenue-neutral change in τ shifts the share of the risk in profits between the firm and the treasury.

It remains to determine the effect of the policy on the equilibrium level of treasury receipts. The latter is distinguished from (4) by writing $\mu_p = \mu_p(X)$, where $X = nx$. This acknowledges that the supply response to the tax change can alter the price distribution, likely in the negative direction. Thus, the equilibrium level of receipts is

$$(9) \qquad \mu_G = n[\mu_p(\bar{X})\bar{x} - c(\bar{x}) - f - Y]\tau \equiv \mu_G(\bar{x}(Y, \tau); Y, \tau).$$

Totally differentiating in (9) and using (5) one obtains

$$(10) \qquad \left.\frac{\partial \mu_G}{\partial \tau}\right|_{dE\{\tilde{G}\}=0} = n\tau\mu_p \left[\frac{\partial \mu_p}{\partial X}\frac{\bar{X}}{\mu_p} + \frac{\mu_p - c'(\bar{x})}{\mu_p}\right] \left.\frac{\partial x}{\partial \tau}\right|_{dE\{\tilde{G}\}=0}.$$

Given the strictly positive term $\partial x/\partial \tau$, the effect on the mean of receipts depends on the magnitude of the terms $(\partial \mu_p/\partial \bar{X})(\bar{X}/\mu_p) \equiv \xi$ and $(\mu_p - c'(\bar{x}))/\mu_p \equiv \lambda$. The first of these is a stochastic analog of the inverse demand elasticity; it likely is negative. The second term is an index of risk aversion adapted from Sandmo [p. 67, equation (11)]; it is nonnegative and increases with increasing risk aversion. Thus, a reduction in the marginal tax rate will lower, leave unchanged, or raise the expected value of equilibrium receipts as ξ is, respectively, less than, equal to, or greater than λ in absolute value.

Concluding Comments

When the firm faces price uncertainty and the decision maker exhibits nonincreasing absolute risk aversion, a revenue-neutral reduction in the marginal tax rate causes the firm to contract output. Given an industry comprised of n such firms, the equilibrium level of transfers between the industry and the treasury may change. The level of these transfers is likely to increase when de-

[2] The author thanks Rulon Pope for this interpretation.

mand for the commodity is inelastic or when producers exhibit low degrees of risk aversion. These results help shed light on a neglected aspect of the 1986 Tax Reform Act, its possible risk-increasing effects. The magnitude of these effects, however, remains an empirical question.

Monetary Impacts on Prices in the Short and Long Run: Some Evidence from New Zealand

John C. Robertson and David Orden

This paper presents support for long-run monetary neutrality based on evidence that individual time series for money, manufacturing prices, and agricultural prices are nonstationary but cointegrated, with a stationary proportional long-run relationship among their levels. Dynamic simulations from a vector error-correction model with this restriction imposed show that monetary shocks shift relative prices in favor of agriculture in the short run and permanently raise nominal prices. Manufacturing price shocks have similar long-run effects but initially place agriculture in a cost-price squeeze, while agricultural price shocks are transitory and have little impact on the other series.

Key words: cointegration, long-run monetary neutrality, unit roots, vector error-correction models.

Whether monetary policy has sustained effects on relative prices has been a crucial question in recent discussions of macroeconomic impacts on agriculture. At issue are whether levels of agricultural and nonagricultural prices respond proportionally to changes in the level of the money supply in the long run, and whether there are predictable deviations from such neutrality in the short run. An important hypothesis concerning these issues is that agriculture is a competitive sector in which its prices are more flexible than those in nonagricultural (fix-price) sectors. Under this hypothesis, it has been argued that expansionary monetary policy favors agriculture and may cause short-run agricultural prices to overshoot their long-run equilibrium levels, while contractionary monetary policy shifts relative prices against agriculture (Bordo; Rausser, Chalfant, and Stamoulis). Alternatively, it has been argued that price shocks arising in oligopolistic nonagricultural sectors, and accommodated by expansionary monetary policy, cause inflation and place agriculture in a cost-price squeeze (Tweeten). The short-run effects of monetary accommodation of supply shocks in agriculture and other competitive sectors have also received attention (Gordon, Van Duyne). None of these arguments about relationships among money and prices in the short run are inconsistent with neutrality in the long run if nominal prices in all sectors eventually reach new equilibrium levels proportional to the money supply. This is the long-run outcome of most theoretical models.

Empirically, a number of recent articles have utilized the impulse response functions from vector autoregression (VAR) models to investigate the relationships among monetary policy and agricultural and other prices in the short run. These articles have presented evidence of non-neutrality in Brazil (Bessler), the United States (Chambers, Orden, Devadoss and Meyers), and Canada (Taylor and Spriggs) but have generally neglected the long-run behavior of money and prices implied by their models. A VAR imposes no testable, theoretically consistent, long-run equilibrium conditions, and estimated long-run results have been viewed in some cases as "nonsensical" (Sims, Mount).

In this paper, the long-run and short-run em-

The authors have benefited from suggestions by Ralph Lattimore, Terry Roe, Robert Myers, Anya McGuirk, John Kitchen, Barbara Craig, and Aris Spanos. An earlier version of this paper was presented at a Reserve Bank seminar and at the 1989 Conference of the Australian Agricultural Economics Society. The authors thank Paul Cruse (Reserve Bank), Rod St. Hill and Bert Ward (Lincoln College), Gary Griffith, Ronald Bewley, and other seminar and conference participants for their comments.

pirical behavior of quarterly levels of money, agricultural prices, and manufacturing prices in New Zealand are analyzed jointly for the period 1963:1–1987:1. The long-run results provide evidence about the theoretical monetary neutrality hypothesis. For New Zealand, the individual money and price series appear nonstationary because of unit roots, as is often the case among aggregate macroeconomic variables (Nelson and Plosser). They also appear cointegrated, so that linear combinations of the series are stationary. Cointegration implies stable equilibrium relationships to which money and prices have a tendency to return (Engle and Granger). The cointegrating relationships found are consistent with long-run proportionality between the level of the money supply and the levels of nominal agricultural and manufacturing prices, and, hence, with neutrality of money in the long run.

Cointegration also has implications for the specification of models of the dynamic relationships among money and prices. These dynamics provide a basis for assessing the various arguments that have been made about short-run deviations from neutrality and are important for New Zealand because of the role of agriculture in the economy. To evaluate these dynamics, while imposing the long-run neutrality restriction, a vector error-correction (VEC) model is specified. In a VEC model, lagged deviations from the long-run equilibrium relationships among the cointegrated variables restrict the interactions within a system of autoregressive equations of first differences of the series. When there is cointegration, a VEC model provides more efficient parameter estimates than a VAR model in levels, while a VAR model in differences ignores information about the levels of the series and is misspecified. Thus, the VEC model provides coherent estimates of the behavior of money and prices in the short and long run. Such inferences are not obtained when support for cointegration among nonstationary series is lacking, as has been the case for money and prices in the United States (Stock and Watson, Orden and Fackler) or for commodity prices among countries (Ardeni).[1]

Organization of the paper is as follows. In the next section, some of the factors affecting the interactions among money and prices in New Zealand are described. In the third section, the stationarity properties of the money and price series are reported and the evidence of long-run monetary neutrality is presented. In the fourth section, the VEC model is specified and short-run non-neutrality hypotheses are evaluated. The final section provides a summary and some conclusions.

Structural Characteristics of the New Zealand Economy

New Zealand is a small and agriculturally trade dependent nation. The farming sector accounts for around 10% of gross domestic product (GDP) and, including processed agricultural products, around 55% of current account receipts. The economy also contains a well-developed manufacturing sector contributing some 25% of GDP. Hence, the sectoral effects of monetary policy and the dynamic relationships between the farming and manufacturing sectors in terms of relative prices, resource allocation, and profitability are important.

Historically, a variety of policies have served to insulate New Zealand from the world economy. Until 1985, domestic monetary policy and a managed exchange rate were closely coordinated and financial markets were tightly regulated. Nominal exchange-rate adjustments were undertaken periodically to maintain a relatively stable, but overvalued, real exchange rate (Rayner and Lattimore).

The manufacturing sector has received relatively high levels of import protection, primarily based on import quotas rather than tariffs. Protection levels for manufacturing have been well above their levels in other OECD countries. The manufacturing sector has also been characterized by a highly centralized wage-setting process with cost-plus-markup pricing policies (Chapple).

In contrast, the agricultural sector has been primarily an export sector and a price taker in international markets. Although a variety o

[1] With the exception of Taylor and Spriggs, who difference their money and price series, the VAR models of short-run monetary impacts cited above were estimated using levels of potentially nonstationary data. A comparative analysis is beyond the scope of this paper, but it would be interesting to examine the robustness of the estimated dynamics from each of these previous studies with an emphasis on tests for nonstationarity and cointegration and model specification based on the results of these tests. Spriggs is currently evaluating whether cointegration affects the specification of his model and has found evidence of cointegration of money and a numbe of disaggregated price series in Canada. For the United States, w do not find evidence of cointegration among nonstationary serie for money and indices of agricultural and manufacturing prices Evidence of structural change during the 1963:1–1987:1 perio complicates making a direct comparison to our results for New Ze land.

support programs have been implemented, agriculture has received relatively low levels of direct producer assistance (Lattimore). With managed exchange rates, volatility in world prices has been reflected in domestic prices. Some exchange-rate adjustments have been undertaken to insulate domestic agriculture from world price fluctuations (for example, the New Zealand dollar was appreciated in 1972–73 and was depreciated in 1975–76). Agriculture has also been subject to various domestic stabilization programs, particularly in the early 1980s, but these policies have never fully offset changes in world prices (Johnson).

With chronic overvaluation of its currency and protection of its manufacturing sector, New Zealand has experienced continual deterioration of its current account balance since the mid-1970s. Widespread wage-price controls were implemented in June 1982 in an attempt to reduce a high domestic inflation rate. These controls became untenable when government deficits reached 9% of GDP and the current account deficit 4.0% of GDP in 1984. As a consequence, the newly elected Labor Government initiated a broad liberalization of the economy aimed at deregulation of financial markets (including floating the New Zealand dollar in March 1985), reduced levels of regulation and direct assistance to specific industries (including elimination of most producer assistance and stabilization programs for agriculture during 1985), and gradual elimination of the import substitution bias of trade policy through reduction of tariffs and other import barriers.

Long-Run Neutrality

The relationships among money and prices in New Zealand were modeled using quarterly data on the money supply, $M1$, manufacturing prices, IP, and agricultural prices, FP. The data are from the Reserve Bank and Department of Statistics data bases and are transformed by taking logarithms. The measure of money is the level of $M1$ (currency plus demand deposits), and the prices are nominal producer output price indices excluding taxes and subsidy payments. The data are plotted in figure 1. Levels of money and the two price indices have risen over time, with agricultural prices exhibiting more variability than manufacturing prices or money.[2]

Long-run monetary neutrality implies a stable equilibrium relationship in which levels of nominal manufacturing and agricultural prices are proportional to the money supply. However, if the individual series are nonstationary because of unit roots, then linear combinations of the series are generally nonstationary and the series have no tendency to move together over time. The long-run neutrality hypothesis requires that some stationary relationships exist among money and prices, which will be the case when the series are cointegrated. For an N-dimensional nonstationary vector Y_t of cointegrated series, one or more vectors $\alpha_i \neq 0$ exists such that $\alpha_i'Y_t = z_{it}$ is stationary (Engle and Granger). The vector α_i is called a cointegrating vector and the z_{it}'s (the error-correction terms) are deviations from the long-run equilibrium. When the series are cointegrated, the long-run relationship $\alpha_i'Y_t = 0$ will tend to be reestablished after disequilibrating shocks. For the neutrality hypothesis to hold requires in addition that the coefficients of the long-run relationship between money and each price series be unity, so that prices are proportional to money in equilibrium.

Stationarity of the Money and Price Series

Tests to determine the stationarity characteristics of the individual money and price series are summarized in table 1. The null hypothesis is that an autoregressive representation of each series contains a unit root. This hypothesis is tested against the alternative that the autoregressive representation is stationary around a linear time trend. The tests are based on OLS-estimated equations in levels reparameterized as

$$(1) \qquad x_t = \beta_0 + \beta_1 t + \beta_2 x_{t-1} + \sum_{i=1}^{p} \beta_{2+i}\Delta x_{t-i} + e_t,$$

where $\Delta x_{t-i} = x_{t-i} - x_{t-i-1}$. A third-order model was selected for money and manufacturing prices and a fifth-order model for agricultural prices based on Sims' modified likelihood ratio tests. Results of the Dickey-Fuller τ_τ test for a unit root ($\beta_2 = 1$) and Φ_3 test of the joint hypothesis of a unit root with drift but no time trend ($\beta_1 = 0$, $\beta_2 = 1$) are reported. The unit-root hypothesis is not rejected at the 0.10 level for any of the series on the basis of either test. Conditional

[2] The initial data was seasonally unadjusted. Possible seasonality in the series was investigated by examining autocorrelation functions and the joint significance of seasonal dummy variables in univariate forecasting equations for each variable. Only the money supply variable exhibited strong seasonality, which was adjusted for via the Holt-Winter smoothing technique as described in Doan and Litterman.

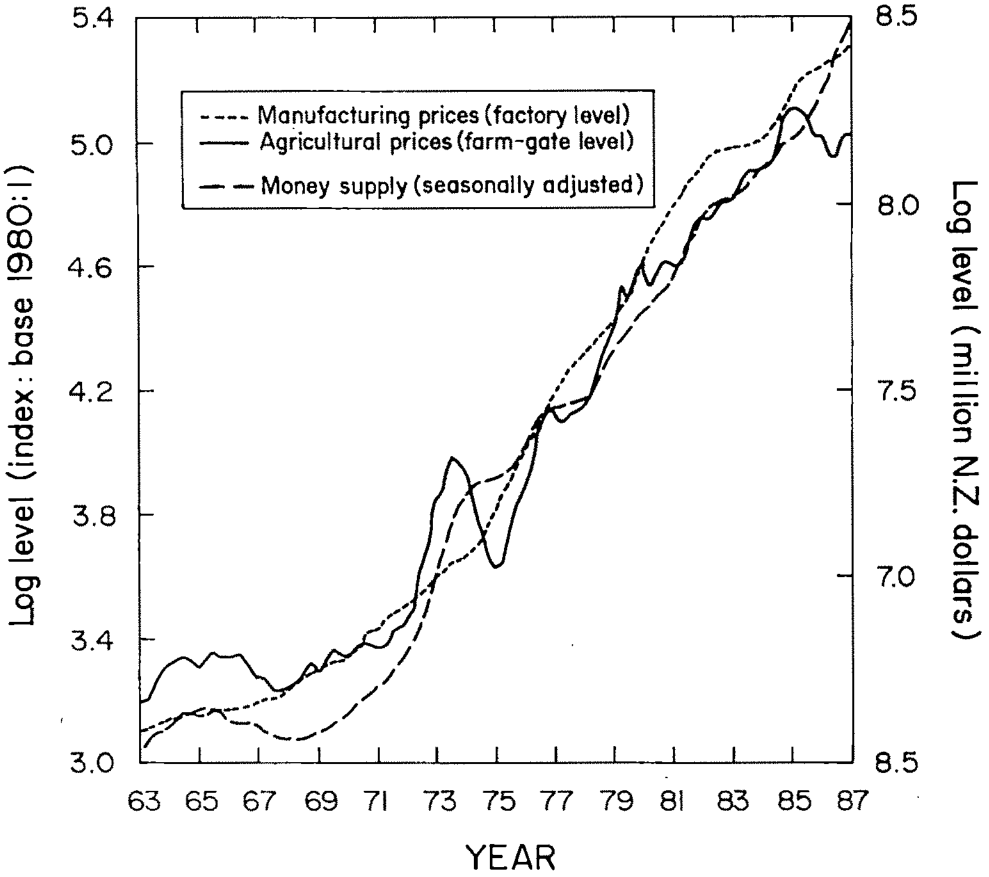

Figure 1. The money supply (*M*1), manufacturing prices, and agricultural prices in New Zealand, 1963:1–1987:1

on this result, a zero drift component is rejected at the 0.05 level for all three series.

Acceptance of the hypothesis that each series contains a unit root is also conditional on the statistical adequacy of the estimated autoregressive models. Therefore, results of several misspecification tests under the null hypothesis (a unit root and drift) are reported in the lower half of table 1. The results generally support the statistical validity of the maintained specifications. The models have reasonable explanatory power, with higher adjusted R^2's and lower estimated regression standard errors for $\Delta M1$ and ΔIP than for ΔFP. Modified Lagrange multiplier tests (denoted *LM*) provide evidence that the errors are not serially correlated (Spanos, p. 542) and skewness-kurtosis tests (denoted *SK*) suggest they are normally distributed (Bera and Jarque). The *ARCH* statistic developed by Engle indicates whether the conditional variances behave autoregressively. The possibility that the variances follow a fourth-order autoregression is not supported, relative to the null that the variances are constant, although there is weak evidence of an *ARCH* effect in the ΔFP equation.

To examine time-dependency of the parameters of the univariate models, tests were undertaken to determine whether the conditional variances are constant over subsamples of relative stability (1964:2–1971:4) and instability (1974:1–1987:1) in the world economy. These tests (denoted *VS*, Spanos p. 484) yielded mixed results; variance stability is rejected for the ΔFP regression residuals at the 0.01 level and the $\Delta M1$ residuals at the 0.05 level. Despite this evidence of instability among the variances, recursive estimation (not shown) indicates quite stable parameter estimates for all three models, except during the 1972–74 period. Moreover, constant variances over the sample and post-sample periods are not rejected when the sample period ends in 1985:4. Chow tests for predictive stability over 1986:1–1987:1 then provide little evidence that changes in the parameters have a

statistically significant impact on the forecasting performance of the models, as shown in table 1. Thus, autoregressive models with time-invariant coefficients provide reasonable representations of the money and price series and the hypothesis that each series contains a unit root is supported.

Cointegration and Neutrality

Tests for cointegration among money, manufacturing prices, and agricultural prices in New Zealand were undertaken conditional on the hypothesis of a unit root and drift in each of the univariate models. Because a cointegrating relationship involves at least two variables, there are at most $r \leq N - 1$ linearly independent cointegrating vectors among N variables. In particular, if money is cointegrated with both manufacturing prices and agricultural prices, the cointegrating relationships can be expressed by

$$\alpha' Y_t = Z_t, \tag{2}$$

where

$$\alpha' = \begin{bmatrix} \alpha_1' \\ \alpha_2' \end{bmatrix} = \begin{bmatrix} 1 & \alpha_{12} & 0 \\ 1 & 0 & \alpha_{23} \end{bmatrix}; \tag{3}$$

$$Y_t = \begin{bmatrix} M1 \\ IP \\ FP \end{bmatrix}; Z_t = \begin{bmatrix} z_{1t} \\ z_{2t} \end{bmatrix}.$$

The vectors α_1', α_2' span the space of cointegrating relationships among money and the two prices. Stock has shown that OLS provides consistent estimates of the cointegrating parameters [$-\alpha_{ij}$ in (3)] in static bivariate regressions of current-dated variables in levels (with a constant included to adjust for differences in means). The residuals from these regressions provide estimates of the error-correction terms, and tests for cointegration are based on testing for a unit root in these series of residuals. Long-run monetary neutrality implies $\alpha_{12} = \alpha_{23} = -1$, while any linear combination of the two vectors provides an equivalent expression of cointegration.

Estimates of the cointegrating parameters from bivariate regressions among the money and price series are reported at the top of table 2. For completeness, the results from all possible bi-

Table 2. Cointegrating Vectors and Tests for Cointegration among Money and Prices

$T = 93(1964{:}1-1987{:}1)$

	Dependent Variable

[a] The coefficient α_{ij} is the only unknown coefficient of a bivariate cointegrating vector [α_i' in (3)] normalized so the coefficient of the dependent variable is one.
[b] Augmented Dickey-Fuller test for a unit root in the residuals from the cointegrating regression. Significance level of the test statistic based on the distribution for $T = 100$ in Engle and Granger; 10% critical value = −2.91.
[c] Single asterisk indicates reject null hypothesis at the 0.10 level; double asterisk indicates reject null hypothesis at the 0.05 level; triple asterisk indicates reject null hypothesis at the 0.01 level.

variate regressions are reported. The estimated cointegrating parameters are concentrated around a value of one, as implied by the neutrality hypothesis, and reversing the dependent and independent variables produces approximately inverse parameter estimates.[3]

Results of the tests for cointegration are reported in the lower part of table 2. For each test, the null hypothesis is no cointegration and the residuals contain a unit root. The alternative hypothesis is that the variables in the corresponding regression are cointegrated and the residuals are stationary. The tests are based on fourth-order autoregressive models of the residuals with the distribution of the Dickey-Fuller test statistic adjusted for its dependence on the estimated cointegrating parameters.

As shown in table 2, the null hypothesis that the residuals contain a unit root is rejected at the 0.01 level for an *IP*,*FP* regression in either direction. For the *M*1,*FP* regressions, a unit root is rejected at the 0.05 level. The results for *M*1,*IP* are less conclusive, but a unit root in the residuals is rejected at the 0.10 level for one of the regressions. Thus, it appears there are long-run equilibrium relationships among the levels of money and prices. Failure to reject a unit root in the residuals of the *M*1,*IP* regressions at the same level of significance as in the other cases may result from the low power of the tests because, by transitivity, if *IP*,*FP*, and *M*1,*FP* are cointegrated, then, equivalently, *M*1,*IP* are also cointegrated.

[3] The parameter estimates also come close to satisfying the transivity that would arise from determining the coefficient of any third equation algebraically from estimated parameters of the two other equations.

Because the estimated cointegrating parameters are close to unity, the long-run relationships between the level of the money supply and of each of the nominal prices are close to proportional. To test the long-run neutrality hypothesis, the parameters were restricted to unity in the cointegrating regressions and the residuals were tested for unit roots.[4] The results for the restricted models shown in table 2 are generally similar to those shown for the unrestricted model and suggest that the money and price series are cointegrated when the proportionality restrictions are imposed. Cointegration is supported at the 0.05 level for the *M*1,*FP* and *IP*,*FP* regressions; however, cointegration is not supported at the 0.10 level for the restricted *M*1,*IP* relationship.

To further explore the evidence of long-run neutrality from the cointegrating regressions among money and prices, a time series for real GNP, as a measure of output, and the relationship between real GNP and the money supply were also examined. A unit root was not rejected at the 0.10 level in a third-order univariate autoregressive model of the real GNP series (the Dickey-Fuller τ_τ statistic was −2.1). Cointegration tests failed to reject the hypothesis that money and real GNP are not cointegrated at the 0.10 level. With a unit root in each series and no cointegration, a model of first differences of

[4] These tests determine only whether or not the neutrality hypothesis is consistent with stationary equilibrium between money and prices. Formal hypothesis tests on the parameters of the cointegrating vectors are difficult to carry out because the asymptotic distributions of the OLS estimators are nonnormal and depend on nuisance parameters that make a general tabulation of critical values infeasible (Stock).

money and real GNP was specified to evaluate the relationship between their growth rates. Granger causality from growth rates of money to growth rates of real GNP was rejected [$F(3,86) = 2.02$]. This lack of evidence of effects of money on output corroborates the long-run monetary neutrality result apparent in the behavior of money and prices.

Dynamics of Money and Prices

Cointegration among the variables in Y_t has several implications for estimation of dynamic models, inference, and forecasting. It implies rank-reducing restrictions on the coefficients of a moving-average representation of Y_t in first differences and on the coefficients of an autoregressive representation of Y_t in levels. Engle and Granger have shown that a useful way to impose these restrictions is by a vector error-correction model of the form

$$(4) \qquad \sum_{s=0}^{P} A_s \Delta Y_{t-s} = -\gamma Z_{t-1} + U_t,$$

where $A_0 = I$, U_t is a vector of one-step-ahead forecast errors, and γ is an $N \times r$ matrix of parameters ($\gamma \neq 0$). Engle and Granger suggest a two-step procedure for estimating a VEC model using the residuals from preliminary cointegrating regressions as estimates of the error-correction terms.

In a VEC model, one-period-lagged deviations from the long-run equilibrium relationships among the cointegrated variables affect the dynamic interactions in a system of equations of first differences of the series through the γ matrix. In this model, short-run dynamics are flexible, while the long-run constraints among levels of the series implied by cointegration are imposed. The model allows the error-correction process that returns the system to equilibrium to be gradual so it can produce accurate forecasts of responses to disequilibrating shocks over reasonable horizons (Hendry). Because all of the terms in the model are stationary, standard asymptotic results for parameter estimation and hypothesis testing apply and the autoregressive model can be inverted, validating dynamic simulations based on a moving-average representation. Sims, Stock, and Watson have shown that standard asymptotic distribution theory can also be applied to a model in levels involving cointegrated variables. However, a VAR in levels omits the constraints on its parameters implied by cointegration. Hence, a levels model produces long-run forecasts that are consistent but are inefficient (Engle and Yoo). A VAR in first differences is nested within the VEC specification but is misspecified for cointegrated series because it omits the error-correction terms.

Based on the evidence of cointegration among money and prices in New Zealand, the two-step procedure was used to estimate a three-variable VEC model by OLS. First differences of each series were regressed against a constant, the error-correction residuals from the restricted *IP,FP* and *FP,M*1 cointegrating regressions, and lags of the first differences of each series. A third-order model was chosen based on Sims' modified likelihood ratio tests and Akaike's information criterion, as shown at the top of table 3.

Estimation results and misspecification statistics for each equation in the VEC model are presented at the bottom of table 3. The adjusted R^2s from the estimated forecasting equations are higher, and the equation standard errors are lower, than those reported for the univariate models for $\Delta M1$ and ΔFP. The *LM* tests provide no evidence that the errors are serially correlated, and the *SK* statistics indicate they are normally distributed. There is more evidence of an *ARCH* effect in the $\Delta M1$ equation and less in the ΔFP equation than in the univariate models, and there remains evidence of conditional variance instability in these equations. However, recursive least squares estimates of the parameters (not shown) are again stable (except during 1972–74) and Chow tests for predictive stability over 1986:1–1987:1 provide no evidence of parameter changes having a significant impact on the predictive performance of the model. Overall, these results imply that the VEC model is a reasonably robust statistical model. The evidence from the cointegration tests that a VEC model is an appropriate specification is supported by rejection of the restriction that the coefficients of the error-correction terms are jointly zero. The calculated likelihood ratio statistic (not shown in table 3) is $\chi^2(6) = 14.73$, which is significant at the 0.05 level.

Structural Specification and Simulation Results

To trace the dynamic effects of various shocks, the estimated VEC model was reparameterized to its equivalent formulation in levels. With this reparameterization, the error-correction terms are incorporated into the first-period lagged terms of the autoregression. The model can then be

inverted to obtain impulse response functions that capture the effects of deviations from long-run equilibrium on the dynamic paths followed by each variable in response to initial shocks.

While tests of the long-run neutrality hypothesis are not dependent on identification of the sources of stochastic deviations from the long-run equilibrium, interpretation of the dynamic relationships from the VEC model requires structural identifying assumptions. Although one must be cautious about structural interpretation because many potential sources of variation are aggregated in the error term of each equation, in the remainder of this analysis the model is interpreted as describing the policy-setting behavior of the monetary authority and reduced-form equations for each sector capturing the likely responses of agricultural and manufacturing prices to shocks of monetary and sectoral origins. Assuming a recursive model then allows a structural interpretation based on a Choleski decomposition of the covariance matrix of the model's one-step-ahead forecast errors.

Impulse response functions showing the responses to one-standard-deviation positive shocks to each variable and their 90% confidence bounds were calculated for the VEC model for several recursive orders using a Monte Carlo integration algorithm with 200 draws from the posterior distribution of each response estimate (Doan and Litterman). The results are essentially invariant to the recursive order and are plotted for the order $M1,IP,FP$ in figure 2 for a twenty-quarter forecast horizon. This model allows money supply shocks the most opportunity to affect the price variables by attributing to the monetary shock any contemporaneous correlations among the forecast errors for money and prices.

The point estimates from the impulse response functions show that the dynamic responses of money and prices depend on the source of the initial shock. The long-run percentage responses to a given shock are approximately equal among the three variables. This reflects the long-run equilibrium imposed by the unitary cointegrating vectors. After any given shock, equality of the point estimates of the impulse responses occurs around thirty quarters.

While further interpretation of the point estimates of the impulse responses shown in figure 2 must be qualified because of their estimated standard errors, the mean responses suggest several observations about the likely time paths of money and prices after specific shocks. In particular, a positive monetary shock raises the levels of the money supply, manufacturing prices, and agricultural prices in the long run. Agricultural prices are immediately responsive to the monetary shock and display some indication of a cylical response pattern, while manufacturing prices start to respond only after a lag of four quarters. With managed exchange rates and agriculture being a price taker in world markets, that positive monetary shocks induce a shift in

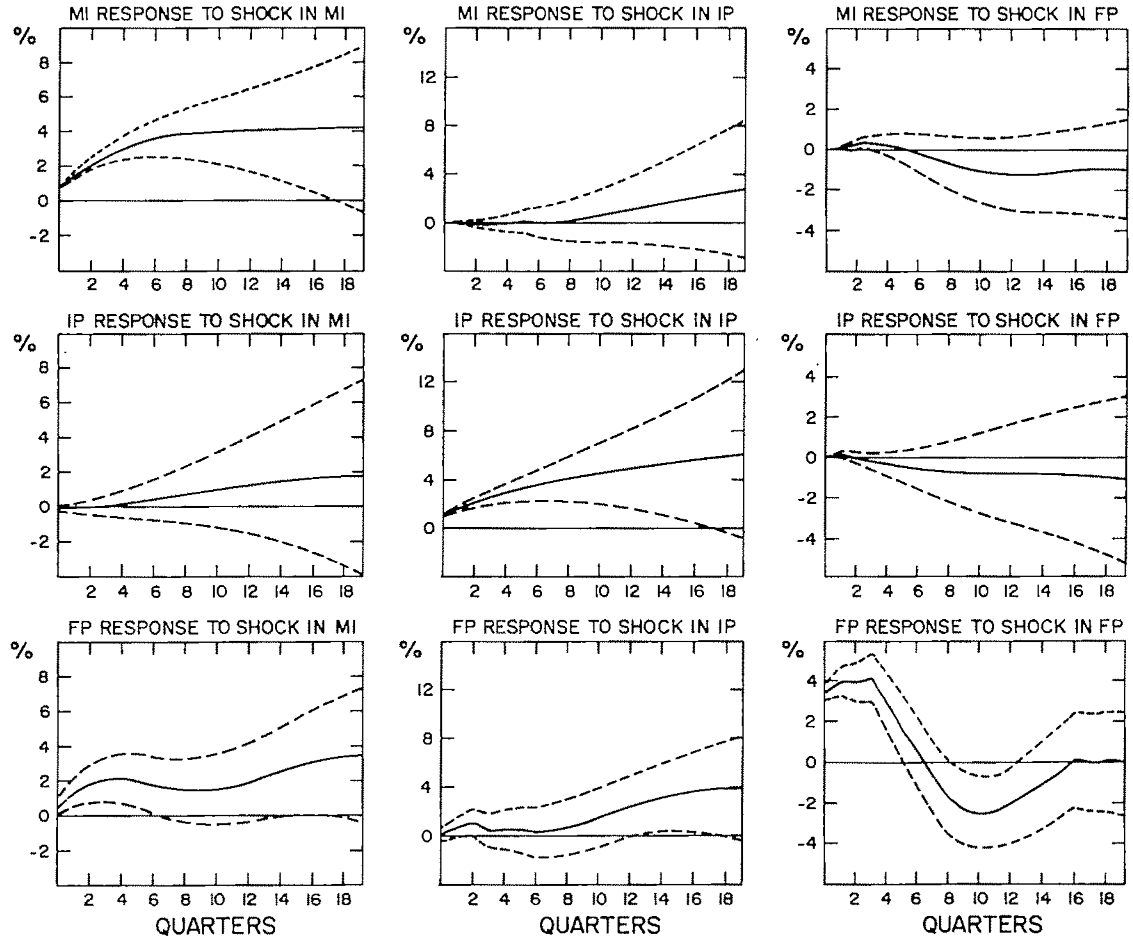

Figure 2. Responses to one-standard-deviation shocks from VEC model of money, manufacturing prices, and agricultural prices

relative prices in favor of agriculture in the short run implies that monetary expansions have been associated with nominal devaluations before domestic manufacturing prices rise. Agricultural prices do not respond more than proportionately or overshoot their long-run equilibrium level in response to a monetary shock, as might be the case if exchange rates were flexible and were to overshoot their long-run equilibrium values in response to monetary policy.

A positive shock to manufacturing prices also raises the levels of all three series in the long run. There is a lag in the response of the money supply and agricultural prices. Because of this delay, the shock to manufacturing prices initially places agriculture in a cost-price squeeze. The response of the money supply suggests a lagged accommodation of the increase in the domestic prices of manufactured goods by the monetary authority, with agricultural prices adjusting simultaneously. This autonomy of manufacturing prices, and subsequent monetary responsiveness, may not persist under the current policies for gradual liberalization of the manufacturing sector, but no evidence of structural change was found through 1987:1.

In contrast to the permanent shift in the level of each series induced by shocks to the money supply or manufacturing prices, following an agricultural price shock a new long-run equilibrium of each series is established around its initial level. The own response of agricultural prices displays a dampening oscillatory pattern. Neither the money supply nor manufacturing prices shows any significant short-run response, so there is a short-run shift in relative prices in favor of agriculture.

The failure to detect an effect of agricultural

prices on the money supply, compared to the long-run responsiveness of the money supply to shocks to manufacturing prices, also has policy implications. The lack of feedback from agricultural prices to the money supply suggests unwillingness of the monetary authority to accommodate world agricultural price shocks. Stabilization programs that retained farm earnings in the Reserve Bank during periods of high world prices and released them during periods of low prices contributed to the ability of the monetary authority to insulate New Zealand from external inflationary and deflationary pressures arising from agriculture. These stabilization programs have been eliminated since 1985. Again, no evidence of structural change was found through 1987:1. However, it remains to be observed whether the dynamic patterns of responses to agricultural price shocks will persist or whether future agricultural shocks will induce greater instability in the money supply or manufacturing prices.

It is interesting to compare the results shown in figure 1 to impulse responses from VAR models specified under alternative assumptions about the stationarity properties of the money and price series. Two VAR models were estimated: a fourth-order model in levels, under the maintained hypothesis of stationarity, and a third-order model in first differences (without the error-correction terms), under the maintained hypothesis of unit roots and no cointegration. The point estimates of the impulse responses from the VAR in levels (not shown but available on request) are generally similar to those from the VEC model. This is not surprising because the parameter estimates from a levels model are consistent for cointegrated nonstationary variables. However, with no long-run restrictions imposed, the point estimates of the impulse responses following any specific shock do not converge to common values in the levels model even after forty quarters.

In contrast, the impulse response functions from a VAR model in first differences are unlike those from the VEC model or the VAR model in levels. Estimates from the differences model (reparameterized to show the impacts of each shock on levels of the variables) suggest both a more-than-proportionate short-run response of agricultural prices to a money supply shock and a short-run tendency for agricultural prices to overshoot their long-run level. The own response to a shock to manufacturing prices is persistent in the differences model and is largely matched by the response of agricultural prices, while the money supply responds more slowly and to a lower level over a long horizon. Own responses to shocks to agricultural prices are also persistent in the differences model but do not induce responses of the money supply or manufacturing prices, suggesting a long-run shift in relative prices in favor of agriculture. Thus, inferences drawn from a VAR model in first differences without the error-correction terms would be different than those drawn from the VEC model.

Summary and Conclusions

In this paper, the stationarity properties of the data have been analyzed in order to test the hypothesis of long-run monetary neutrality and better understand the dynamic relationships among money and prices in New Zealand in the short and long run. Tests for stationarity failed to reject a unit root in autoregressive models of the individual series for money, agricultural prices, and manufacturing prices. The money and price series also appear cointegrated, with parameter estimates from unrestricted cointegrating regressions close to unity. When proportionality among levels of money and prices is imposed on the cointegrating regressions, the evidence is weaker but the restricted error-correction terms (residuals) also appear stationary. These results provide empirical support for the long-run monetary neutrality hypothesis.

Incorporating the restricted error-correction terms in a VEC model provides a description of the dynamic relationships among money and prices consistent with long-run neutrality. Monetary shocks raise the levels of prices in the long run. Agricultural prices respond more quickly than manufacturing prices, but no evidence was found that agricultural prices rise proportionately more than the money supply or overshoot their long-run levels in the short run. Shocks to manufacturing prices induce monetary expansions and place agriculture in a short-run cost price squeeze, while levels of the money supply and manufacturing prices have not responded to fluctuations in agricultural prices. These results are consistent with the historical insulation of the manufacturing sector in New Zealand and with policies to stabilize the economy in face of external shocks. Monetary responses to shocks to manufacturing prices may moderate under recent liberalization policies, and these policies may leave the economy more exposed to external shocks, but no evidence was found that policy

reforms have altered the dynamic patterns among money and prices through 1987:1.

The importance of preliminary evaluation of the stationarity properties of the money and price series is demonstrated in this analysis by a comparison of the impulse response functions from the VEC model to those from VAR models estimated under alternative stationarity assumptions. The VEC model provides more precise long-run estimates than an unrestricted VAR model in levels. The impulse response functions from a VAR model in first differences are less plausible than those of the VEC model.

Some caveats about the results also should be noted. The acceptability of an empirical model is tentative until it has been successfully tested against rival models. The VEC model presented in this paper is a small closed system that omits other theoretically relevant variables and aggregates many potential sources of variation in each of its error terms. Inferences from the model are also limited by the recursive structure imposed and by the relatively wide confidence bounds of the impulse response functions. Assuming that the data are rich enough to reveal the underlying phenomena of interest, postulating larger dynamic models with appealing contemporaneous structures and statistical properties is a priority for future research. These models will further our understanding of monetary effects on agriculture, feedback among sectors, and feedback from the sectors to monetary policy.

Risk Analysis of Tillage Alternatives with Government Programs

Jeffery R. Williams, Richard V. Llewelyn, and G. Art Barnaby

Stochastic dominance analysis of two tillage systems, conventional tillage and no-tillage, for five crop rotations, wheat-fallow, grain sorghum-fallow, continuous wheat, continuous grain sorghum, and wheat-grain sorghum-fallow, shows that risk-averse managers prefer a conventional tillage wheat-sorghum-fallow system. Small changes in production costs or yields lead to indifference between this system and the no-tillage wheat-sorghum-fallow and no-till and conventional wheat-fallow systems. Participation in the basic government commodity program generally increases average net returns and lowers variation of returns. Government commodity program payments calculated under a variety of scenarios do not generally encourage the use of no-till practices for grain sorghum and wheat in the central Great Plains.

Key words: commodity programs, conservation tillage, grain sorghum, no-tillage, risk, stochastic dominance, wheat.

Dryland production of wheat and grain sorghum in the Great Plains is dependent on sufficient soil moisture. Low humidity and high winds contribute to the loss of soil moisture and soil erosion in this region. Conservation tillage systems, including no-tillage, reduce the potential for soil erosion and soil moisture loss. Economic evaluations of no-tillage systems are important in order to determine their effects on the level and variability of farm returns. Current government program provisions do not directly restrict tillage system selection, although they do affect crop decisions by dryland wheat-fallow farmers in the Great Plains. In addition, the assigned program yield provision can penalize a farm manager who selects a tillage system which requires and generates higher yields for increased net returns. The risk-reducing characteristics of the program influence tillage system and crop rotation selection as well.

Economic analysis of conservation tillage under government program provisions has not been well documented for no-tillage wheat and grain sorghum rotations. Studies have shown that conservation tillage generally increases wheat and grain sorghum yields relative to conventional tillage, although this is not consistently the case (Reed and Erickson; Baumhardt, Zartman, and Unger). Higher yields were attributed to higher soil moisture at planting. Variable costs have been higher for reduced tillage wheat systems; but, when machinery costs were considered, some systems were competitive (Epplin et al.). Harman compared conventional and conservation tillage grain sorghum and found significant cost reductions on the conservation tillage systems. Williams analyzed dryland tillage systems for wheat and grain sorghum in western Kansas both with and without the use of crop insurance. He concluded that risk-averse managers would prefer reduced tillage systems, given the reduced costs and increased yields. Helms, Bailey, and Glover considered the impact of government commodity programs on conservation tillage practices for a dryland wheat farm in Utah, using whole-farm simulation. They conclude that risk-averse producers prefer a combination of minimum and no-tillage with program participation. However, their study used identical yield distributions for each tillage practice, rather than actual yield data from specific tillage systems. Alternative crop rotations were not considered.

This study compares wheat and grain sorghum

The authors are, respectively, a professor, a former research assistant, and an associate professor, Department of Agricultural Economics, Kansas State University.

rotations grown continuously, in fallow systems, and in rotation using conventional and no-tillage methods. The impact of the 1985 Food Security Act commodity provisions on tillage system and crop rotation is also evaluated. The objective is to analyze the risk and returns of each system and the consistency of the results with the soil conservation objectives of the act. Net return distributions are first generated using historical commodity prices and then calculated using the government program provisions for the 1987 crop year. Stochastic dominance techniques are used to determine the preferred systems.

Tillage and Rotation Practices

Conventional and no-tillage practices are considered for five crop rotations. The resulting combinations of tillage and crop systems are (*a*) conventional tillage wheat-fallow (CVWF), (*b*) no-till wheat-fallow (NTWF), (*c*) conventional tillage continuous wheat (CVWW), (*d*) no-till continuous wheat (NTWW), (*e*) conventional tillage continuous grain sorghum (CVSS), (*f*) no-till continuous grain sorghum (NTSS), (*g*) conventional tillage grain sorghum-fallow (CVSF), (*h*) no-till grain sorghum-fallow (NTSF), (*i*) conventional tillage wheat-grain sorghum-fallow (CVWSF), and (*j*) no-till wheat-grain sorghum-fallow (NTWSF).

Typical conventional tillage operations for western Kansas consist of primary tillage using a V-blade sweep or disk and secondary tillage using a rodweeder in wheat and a disk in grain sorghum. Cultivation along with a single application of herbicides occurs during the growing season for weed control in sorghum. In no-tillage, weed control is achieved through herbicide application during the fallow period and prior to planting.

The length of the fallow period is a major distinction between the various crop rotations. The traditional wheat-fallow system involves a fifteen-month fallow period between harvest in July and planting the next crop in September of the following year. The sorghum-fallow system has a nineteen-month fallow period between harvest and planting. The continuous systems have no extended fallow period because the entire acreage is planted to a crop each year. Wheat-sorghum-fallow rotations have an eleven-month fallow period between wheat harvest and planting of grain sorghum and another eleven-month fallow period occurs between sorghum harvest and whea planting.

Procedures and Data Requirements

Variable inputs and general equipment require ments are determined for each cropping system based on practices of the Kansas Agricultura Experiment Station. Variable and fixed costs ar determined with regard to farm size and tenu arrangements. Specific costs for individual fiel operations are calculated and organized into whole-farm budget for each cropping and tillag combination.

Distributions of net returns to land and mar agement for each system are calculated usin yield and price data from 1976–86 and 198 costs, under both participation and nonpartic pation in the commodity program. Loan rates target prices, and acreage reduction percentage for the 1987 cropping year are used in these ca culations.

Four scenarios involving participation an nonparticipation in the government commodit program are examined: (*a*) nonparticipation, (*l* participation with an established base in a whea fallow rotation, (*c*) participation with a bas change approved to comply with soil conse vation requirements, and (*d*) participation in th optional paid land diversion for grain sorghu in addition to the conditions of scenario *c*.

Equation (1) described how each observatio of net return is estimated for both crops in eac cropping system under the government progra provisions for owned land. Returns to the o erator including deficiency and diversion pa ments on rented land are shared with the lan lord in the same ratio as yield-increasing inp costs.

$$(1)\quad \sum_{i=1}^{2} NR_{in} = \sum_{i=1}^{2} \{[(\max\{P_{in}, EL_{iN}\} * Y_{in}) - VC_{iN} - FC_{iN}] * PA_{iN} - [(MC_{iN} + FC_{iN}) * (ARP_{iN} + OPD_{iN})]\} + PAY_{in},$$

where

$$PAY_{in} = \{[DP_{in} * PA_{iN}] + [OPD_{iN} * OPDR_{iN}]\} * PY_{iN}.$$

If $\Sigma_{i=1}^{2} PAY_{in} > \$50{,}000$, then

$$\sum_{i=1}^{2} NR_{in} = \sum_{i=1}^{2} \{[(\max\{P_{in}, EL_{iN}\} * Y_{in}) - VC_{iN} - FC_{iN}] * PA_{iN} - [(MC_{iN} + FC_{iN}) * (ARP_{iN} + OPD_{iN})]\} + \$50{,}000 + \min\left\{\sum_{i=1}^{2} [(FL_{iN} - EL_{iN}) * PY_{iN} * PA_{iN}], \$200{,}000\right\},$$

where

- i = 1, 2 (1 is wheat and 2 is grain sorghum);
- n = 1, ..., N (N = 11 years);
- NR_{in} is net returns, crop i ($) for observation n;
- P_{in} is market price, crop i ($/bu.), for observation n;
- EL_{iN} is effective national average loan rate ($/bu.);
- Y_{iN} is average yield on planted acreage (bu./acre);
- VC_{iN} is variable costs of production ($/acre);
- FC_{iN} is fixed costs ($/acre);
- PA_{iN} is planted acres, crop i, where $PA_{iN} = BA_{iN} - ARP_{iN} - OPD_{iN}$;
- BA_{iN} is base acres, crop i;
- ARR_{iN} is acreage reduction requirement (% of BA_i);
- OPD_{iN} is optional paid diversion (acres);
- ARP_{iN} is acreage reduction program acres, where $ARP_{iN} = ARR_{iN} * BA_{iN}$;
- $OPDR_{iN}$ is optional paid diversion payment rate ($/bu.);
- MC_{iN} is maintenance cost for diverted acres ($/acre);
- PAY_{in} is government payments ($);
- DP_{in} is deficiency payments ($/bu.), where $DP_{in} = TP_{iN} - \max\{P_{in}, EL_{iN}\}$;
- TP_{iN} is target price ($/bu.);
- EP_{iN} is expected national average price ($/bu.);
- PY_{iN} is program yield (bu./acre); and
- FL_{iN} is formula loan rate ($/bu.).

Yields (Y_{in}) are used to calculate the gross returns on the crop actually produced. Market prices (P_{in}) are assumed to be the season average price. When returns are calculated under the government program provisions, the market price is not allowed to fall below the effective loan rate (EL_{iN}). The formula loan rates (FL_{iN}) for 1987 were $2.85 per bushel for wheat and $2.17 per bushel for grain sorghum. Effective loan rates (EL_{iN}) are $2.28 per bushel for wheat and $1.74 per bushel for grain sorghum. Target prices (TP_{iN}) were $4.38 per bushel for wheat and $2.88 per bushel for grain sorghum. The percent set-aside was 27.5% of base acres for wheat and 20% for grain sorghum in 1987. A detailed discussion of government program provisions is provided in Williams, Harper, and Barnaby.

Stochastic dominance analysis is used in each case to select efficient strategies by comparing the cumulative density functions (cdf) of possible returns for each strategy. This study uses second-degree stochastic dominance (SSD) and stochastic dominance with respect to a function (SDRF), (Cochran, Robison, and Lodwick). The solutions for the stochastic dominance analysis are found using an optimal control algorithm developed by Raskin, Goh, and Cochran.

Yields and Prices

Yield and soil moisture data were obtained from the Fort Hays Branch Experiment Station at Hays, Kansas. Crop prices are the season averages from the central district of the Kansas Crop and Livestock Reporting Service. The prices are converted to 1986 dollars using the U.S. Department of Agriculture (USDA) index of prices received by farmers.

Yield and soil moisture data are analyzed using Duncan's multiple range test to determine if the means for crop yields or soil moisture differed significantly under the ten crop systems (table 1). Continuous wheat and continuous grain sorghum have significantly lower yields than the other crop rotations. In examining tillage systems, no-tillage wheat-fallow yields are significantly higher than those of conventional tillage wheat-fallow. No significant differences occurred between yields for the other wheat rotations or sorghum due to tillage practices. Average soil moisture in no-tillage systems is significantly higher than in conventional tillage systems for each crop rotation (table 1).

The use of experiment station yield data for this type of analysis is a source of concern. Although farm data for similar tillage practices are not available for comparison with experiment plot data, yield data for dryland fallow wheat from thirty-five farms in west-central Kansas are available. The mean yield (based on harvested

[a] CVWF is conventional tillage wheat-fallow; NTWF, no-tillage wheat-fallow; CVWW, conventional tillage continuous wheat; NTWW, no-tillage continuous wheat; CVSS, conventional tillage continuous sorghum; NTSS, no-tillage continuous sorghum; CVSF, conventional tillage sorghum-fallow; NTSF, no-tillage sorghum-fallow; CVWSF, conventional tillage wheat-sorghum-fallow; NTWSF, no-tillage wheat-sorghum-fallow.

[b] Duncan's Multiple Range Test performed for $\alpha = .05$. Letters A–E indicate the grouping of the mean. A mean with the letter A is statistically different than a mean with any other single letter such as B, and a mean with the letter B is statistically different than a mean with letter C, etc. A mean with the letter AB is not statistically different from a mean with the letter A or B but is statistically different from any other letter or combinations of letters not containing A or B.

[c] Average annual yield.

[d] Average soil moisture (inches) in a 6-foot soil profile at planting time.

[e] Net return to land and management equals gross income minus all costs except for a land and management charge, including opportunity cost on operator labor, interest expense on variable inputs, and equipment. Numbers in parentheses are for comparison only between tillage systems given the same crop rotation, or within tillage system and crop rotation across program scenarios.

acres) for dryland wheat is 34.9 bushels per acre with a standard deviation of 8.8 for continuous farm data from 1976 to 1986. This compares with average conventional tillage wheat yields on the experiment station of 29.2 bushels per acre and no-till wheat yields of 33.1 bushels per acre during the same period. Standard deviations for the experiment station data are 8.8 for conventional tillage and 7.2 for no-till. Thus, the experiment station data provide reasonable estimates of relative yield variability for the comparison of tillage and cropping systems. Sorghum yield data are not available for comparison.

Size and Tenure Characteristics

Kansas Farm Management Association data compiled by Langemeier for 130 predominantly dryland farms in west-central Kansas are used to establish the size and tenure arrangements of the representative farm. The average farm contains approximately 1,100 acres of cropland of which 33.4% is owned. The remainder is rented, typically using a crop share arrangement.

Costs

Specific tillage methods, fertilization, chemical, and seeding rates are obtained from practices at the experiment station. An equipment complement for each system is based on acreage, equipment efficiency, and time available to complete the field operations (Schrock). Labor requirements are estimated from the total time required for field operations for the necessary equipment complement. Data from Schrock, Kramer, and Clark are used to calculate per acre fuel requirements for each tillage operation. Harvesting and fertilizer application costs are based on the typical west central Kansas practice of custom hiring for these operations.

Equipment costs include charges for depreciation, average annual interest (opportunity costs), insurance and housing, and repairs. A depreciable value was determined by discounting the list price by 30% for tractors and 20% for other machinery. All equipment ages were assumed to be half of their depreciable life: tractors—five years, planting equipment—six years, and tillage implements—seven years. All equipment not used in the conventional tillage wheat-fallow system is assumed newly purchased. List price is deflated to the appropriate year of purchase to determine the original value for depreciation purposes. Salvage values are estimated as a percentage of purchase price (Bauscher and Willet). Repairs are estimated by using the hours of use for tractor and tillage implement in each field operation, initial list price, and total hours of machine use (Rotz).

Analysis and Results

In this section the results of the empirical analysis are reported for the various cropping systems under alternative provisions for the government programs.

Nonparticipation in Government Commodity Program

Conventional wheat-sorghum-fallow (CVWSF) has the highest net return followed by no-till wheat-sorghum-fallow (NTWSF) (table 1, No Gov't.). These systems also have the fewest number of losses. However, these systems have much higher standard deviations than the wheat-fallow system, indicating higher potential risk. All of the systems with sorghum included have higher standard deviations than the wheat-fallow systems.

Stochastic dominance analysis is used to find the SSD and SDRF efficient sets (table 2, No Gov't.). The efficient set in SSD includes the NTWF, NTWSF, and CVWSF systems. For SDRF, the CVWSF system is dominant in all risk intervals.

Nonparticipation Sensitivity Analysis

The magnitude of a parallel shift of the dominant distribution necessary to eliminate its dominance is also considered. In the risk preference interval of 0.00001 to 0.00005, the results are quite sensitive to changes in yield or production costs between the dominant CVWSF system and the NTWSF system. If the cdf for CVWSF is lowered by a parallel shift of \$528, it no longer dominates the NTWSF system. This is equivalent to a \$1.44 per acre increase in cost, a .47 bushels per acre wheat yield reduction, or a .71 bushels per acre sorghum yield reduction (given average crop prices). These yield differences are less than the critical difference (determined using Duncan's Multiple Range Test, $\alpha = .05$) of 3.17 bushels of wheat and 11.74 bushels of grain

Table 2. Stochastic Dominance Results of Commodity Program Participation and Nonparticipation Scenarios

[a] The government program scenario assumes base acreage exists for wheat only.

sorghum required for the yields from these systems to be significantly different. A change in yield smaller than the significant difference between yields for these system changes the preferred system. Therefore, a producer's ability to manage a specific tillage practice and crop rotation effectively may make a substantial difference in the preferred system. A similar parallel shift of $13.63 per acre (i.e., 4.41 bu./acre of wheat or 6.71 bu./acre of sorghum) includes the NTWF system in the efficient set.

Similar sensitivity is also demonstrated in the risk-averse interval, 0.00005 to 0.0001. If the CVWSF distribution is lowered by a parallel shift of $4,394 the NTWSF, NTWF, and CVWF systems enter the efficient set. This is equivalent to a yield reduction of 3.88 bushels per acre for wheat or 5.91 bushels per acre for sorghum.

Diversification

Stochastic dominance involves pair-wise comparisons of cdf's for specific alternatives. If the alternatives can be combined, stochastic dominance should be conducted on diversified portfolios as well. A test of whether dominance of one alternative over another implies dominance over all linear combinations of the two is found in McCarl et al. Correlation coefficients of the strategies are compared to the ratio of their standard errors. If the correlation coefficient is less than this ratio, diversification among the strategies should be addressed.

The test indicates that diversification is possible between NTWSF and NTWW. Some combination of these two systems may be feasible with the NTWSF equipment complement but not with the NTWW complement. Combinations of 10% NTWW and 90% NTWSF, 20% NTWW and 80% NTWSF, and 30% NTWW and 70% NTWSF were analyzed with the pure strategies. None of the combinations are efficient for any of the preference intervals.

Basic Commodity Program Participation

Under current government commodity program provisions, base acreage is based on cropping patterns for the previous five years. Under these provisions, a change in tillage system does not affect base acreage. However, if cropping rotations changed, the farm would not be eligible for the government program. Changing rotations from a wheat fallow base in this study would require planting more acres than are in the wheat base or planting another program crop (sorghum) which has no established base.

Given program constraints and the assumption of a wheat-fallow rotation with a wheat base of 550 acres, the farm can choose participation or nonparticipation with conventional or no-tillage operations in the wheat-fallow sequence or nonparticipation in any other tillage and crop rotation combination. The program yield (PY_{IN}) for both conventional and no-till wheat-fallow systems is the historical average of the conven

tional wheat-fallow rotation. Deficiency payments are calculated using the program yield. Even if tillage systems were changed, the deficiency payment at least in the near future would still be based on yields from conventional tillage.

Under these government program constraints, the NTWF and CVWF systems with government payments enter the efficient sets in the more risk-averse intervals (table 2, Gov't. Prog.). The CVWSF system without program payments is preferred in the less risk-averse intervals. The average net return of the CVWSF system is \$12,490 compared to the \$2,549 and \$730 for the CVWF and NTWF systems in the government program (table 1). The coefficient of variation declines for the CVWF system but increases for the NTWF system when compared to nonparticipation because of the assigned program yield. The government commodity program does not generally encourage the use of no-tillage practices for wheat fallow systems in this situation.[1] Rather, program participation encourages the use of wheat-fallow system as opposed to the somewhat more erosive conventional wheat-sorghum-fallow systems in the more risk-averse intervals (table 2).

Basic Commodity Program Participation Sensitivity Analysis

Sensitivity analyses indicate the results are very sensitive within the range of yields defined by the critical difference, cited earlier, of 3.17 bushels of wheat and 11.74 bushels of grain sorghum. In the risk preference interval 0.00001 to 0.00005, NTWSF and CVWF-G are in the efficient set if the dominant distribution (CVWSF) is lowered by a parallel shift of \$3,304. This is equivalent to a \$9.03 per acre increase in cost, a \$2.92 bushels per acre reduction in wheat yield, or a 4.45 bushels per acre reduction in sorghum yield. In the interval .00005 to .0001, where CVWSF and CVWF-G are dominant, a \$2,170 shift would include NTWSF, NTWF-G, and NTWF in the efficient set.

[1] Risk-averse managers who currently wish to maintain program base acres in a wheat-fallow rotation would prefer a no-tillage system if the program yield reflected the historical yield of the NTWF system rather than the CVWF system. When the historical NTWF yield is used, rather than the CVWF yield for the assigned program yield, and nonparticipation is ruled out, the NTWF system is dominant in the two highest risk-averse intervals.

Commodity Program with Base Acreage Change

A scenario with no restrictions on base acres and program yields is examined because no-tillage techniques in alternative crop rotations may be used to meet the erosion restrictions of a required conservation plan. The local Agricultural Stabilization and Conservation Service (ASCS) committee and state ASCS office may approve a change in base acres if the tillage and cropping system plan is approved by the Soil Conservation Service (SCS). Under this scenario, the farm manager can select the tillage system and crop rotation desired to meet the requirements of the farm's conservation plan.

Base acreage is 550 acres for crop-fallow systems, 1,100 acres for continuous crop systems and 366.7 acres for each crop in the wheat-sorghum-fallow system. The program yield (PY_{iN}) used to calculate the deficiency payment for a new tillage system and cropping practice is assumed to be based on the historical yields from the appropriate experiment station. In this case, PY_{iN} is the historical mean of the yield from each crop rotation and tillage system combination. All other requirements of the government commodity program (including set-aside acreage) remain the same.

The change in base acreage increases net return substantially in comparison to nonparticipation (table 1, Base Change). The CVWSF system with government payments is now preferred in all risk-averse intervals (table 2, Base Change). The NTWF and CVWF systems with government payments are no longer in the efficient set for the most risk-averse interval. However, this system would not be approved because the production of grain sorghum in a conventional tillage system is considered more erosive than no-tillage wheat-fallow or conventional wheat-fallow. Additional inconsistencies between crop production activities which are less erosive and commodity program benefits are addressed by Reichelderfer.

Commodity Program with Paid Land Diversion

The 1985 farm bill also contains an optional paid land diversion for feed grains. Designed to further reduce crop surpluses, this policy may reduce risk by providing a fixed payment to producers who voluntarily divert an additional 15%

of their feed grain acreage base to conservation use. Payment for the additional acres is based on the payment rate ($OPDR_{iN}$), acres diverted (OPD_{iN}), and program yield (PY_{iN}) [equation (1)].

These provisions apply to grain sorghum in this analysis. Optional diverted acres (OPD_{iN}) are 15% of the base acreage and the optional paid diversion rate ($OPDR_{iN}$) is \$1.90 per bushel. Planted acres are now equal to the acres planted under the previous situation (PA_{iN}) less the additional acres diverted (OPD_{iN}). Total set-aside acres now equal the initial set-aside acres (ARP_{iN}) plus the diverted acreage (OPD_{iN}). There is no optional paid diversion for wheat.

When these provisions are included, average net returns in table 1 for the systems including sorghum (15% diversion) are smaller than under the government program without the optional diversion (Gov't. Program); however, their variability is decreased due to the removal of price and yield variability from the additional diverted acres. Optional paid diversion reduced both the maximum loss and maximum gain. Lower net returns occur because the reduction in gross returns due to the diversion payment being lower than the average grain sorghum price exceeds the reduction in costs from diverting planted acres to set-aside acres.

A scenario allowing a change in base acreage and program yield plus the optional paid land diversion also is evaluated (table 2, Paid Land Diversion). In this scenario, the SSD-efficient strategies are conventional tillage wheat-sorghum-fallow, with the basic government program and with the additional 15% paid land diversion (CVWSF-G, CVWSF-D). Very strongly risk-averse producers would prefer the CVWSF system with the optional paid land diversion. In less strongly risk-averse intervals the basic gover ment program is preferred or indifferent to t program with the optional paid diversion. Sin this conventional tillage system has more er sive characteristics than a wheat-fallow syster the change would not be approved as part of soil conservation plan.

Tillage System Selection

The risk-efficient set of cropping rotations f each tillage method and the efficient set of t lage methods for each crop rotation are al evaluated. Under nonparticipation the whea sorghum-fallow cropping sequence is preferr in most risk-averse intervals for both the co ventional and no-tillage systems (table 3). T preferred tillage system varies by crop rotatio The no-till system is preferred for the whea fallow, continuous wheat, and continuo sorghum rotations, while the conventional t lage system is preferred for the sorghum-fallo and wheat-sorghum-fallow rotations. These r sults suggest that the conventional tillage syste is desirable when sorghum is included in a fa low cropping system.

Program participation is also evaluated l cropping rotation (table 4). Base acreage is a nual planted crop areas; 550 for crop-fallow sy tems, 1,100 for continuous systems, and 366 acres for each crop in the wheat-sorghum-fallc systems. The program yield used in calculati deficiency payments is the historical average fro the conventional tillage system for each crop r tation.

Stochastic dominance analysis indicates th the conventional tillage system including go

Table 3. Stochastic Dominance Results by Tillage System and Crop Rotation for Nonpa ticipation

Lower $R(x)$		Upper $R(x)$	Tillage Method CV	NT	Crop Rotation WF	WW	SF	SS	W

0.0001	to	0.001	CV-G, NT-G	CV-G	CV-G	CV-G	CV-G	CV-D	CV-D	CV-D

Note: CV is conventional tillage; NT, no tillage; WF, wheat-fallow; WW, continuous wheat; SF, sorghum-fallow; SS, continuous sorghum; WSF, wheat-sorghum-fallow; -G, indicates distributions with basic government program participation; -D, indicates distributions with government program participation including paid land diversion for feed grains. These results indicate the preferred tillage system with or without the government program given that the indicated crop rotation is the only option available because of established base acres.

ernment program payments is preferred for most crop rotations. The no-tillage system is included in the most strongly risk-averse interval for the wheat-fallow rotation, and in two less risk-averse intervals for the continuous sorghum system (table 4). When these results are compared with those in table 3, government program participation tends to discourage no-tillage practices.

The impact on tillage practice selection by the commodity program with the optional paid land diversion is also evaluated for rotations including sorghum (table 4; SF-G-D, SS-G-D, and WSF-G-D). Conventional tillage is generally preferred for most crop rotations with the exception of the continuous sorghum sequence. The optional paid land diversion is generally selected in the more risk-averse intervals and the basic government program in less risk-averse intervals.

Concluding Comments

A conventional wheat-sorghum-fallow system is generally preferred by risk-averse managers when government program payments are not considered. When government commodity program provisions are included very highly risk-averse individuals prefer the no-till wheat-fallow and conventional wheat-fallow rotations. However, in less risk-averse intervals, the conventional tillage wheat-sorghum-fallow system without government program payments is preferred. These results are quite sensitive to production cost and yield changes.

Although the conservation compliance provisions of the 1985 Food Security Act have the objective of reducing soil erosion, the commodity program provisions do not encourage the use of no-tillage systems for wheat and sorghum in this region. This study finds that the commodity program assigned yield provision discourages the use of no-till practices for wheat rotations. Producers who diversify with no tillage grain sorghum would also be adversely affected by this provision. The risk reduction characteristic of the optional paid land diversion contributes to risk-averse managers preferring rotations including more erodible sorghum enterprises instead of rotations that are exclusively wheat, which has no optional paid land diversion. A change in base acres and program yield allowed by an approved conservation plan does not provide sufficient incentive for using a no-tillage system in the wheat-grain sorghum-fallow rotation.

The reader is reminded that the only behavioral attribute considered in this study is risk attitude with regard to income. Farmers have multiple farm management objectives including managing financial risk, soil conservation, and maintaining government program eligibility (institutional risk) which deserve evaluation. The current commodity program rule which restricts switching base acres to maintain program eligibility is a major factor which encourages the continued use of wheat, which is less erosive than grain sorghum, on traditional wheat-fallow farms as opposed to diversifying with a more erodible grain sorghum enterprise.

Agricultural Production Technologies with Systematic and Stochastic Technical Change

Chris Fawson, C. Richard Shumway, and Robert L. Basmann

A production system modeling tool is developed that implements recent work on autoregressive and endogenous stochastic production technologies associated with generalized Fechner-Thurstone (GFT) optimizing functions. A GFT-class production system is used to evaluate the empirical support for technology specifications inherent in the neoclassical theoretic structure of an agricultural production region. Little likelihood support is found for zero serial correlation, elimination of systematic technology changers from the production system, strict neoclassical production technologies, Hicks-neutral technical change, or zero homogenous factor demand functions.

Key words: endogenous technology, generalized Fechner-Thurstone, primal, technical change.

Economic theory provides a rigorous and unambiguous logical structure in which to model optimizing production behavior. It identifies equivalent methodological foundations for examining behavior, implies within and cross-equation restrictions, and even suggests likely data correlations and error relationships. Nevertheless, economic theory is insufficient alone to provide unambiguous model specifications or a complete statistical foundation for examination of production technology.

In most cases where systems of partial derivative equations implied by the theory have been estimated in order to derive implications about technology, a time trend has been included as a regressor to capture information on technical change and a random error has been appended to the estimation of optimizing conditions. The continuing use of this procedure ignores a growing body of literature that calls into doubt the conventional causal interpretation of time trend parameters and the important body of literature addressing the stochastic nature of production technology that dates to work in the mid-1960s by Mundlak and Hoch and by Zellner, Kmenta, and Dreze.

In addition, continued use of conventional methods perpetuates the naive assumptions that (*a*) producers are unable to compute optimal solutions even when they know the true functional specifications of nonstochastic production technologies, and (*b*) changes in aggregate technology remain invariant to changes in exogenous economic variables. Because of rapidly changing microproduction processes and techniques, long production periods, and dependence on the vagaries of weather, it is likely that the primary uncertainty in agricultural production centers on the technology itself. Further, because of both systematic and stochastic variation of the agricultural production technology, changes in exogenous economic variables may provide incentives for producers to alter their choice of specific production techniques from among the complete set of available microproduction processes comprising the aggregate technology. The choice of microproduction processes then defines the ob-

Texas Agricultural Experiment Station Technical Article No. 22214.

This research was supported by the Texas Agricultural Experiment Station and a grant from the Economic Research Service, U.S. Department of Agriculture.

The authors are indebted to Pablo Gottret and Enrique Ospina for assistance in compiling the data used in this study; to John Johnson for computational assistance; and to David Bessler, Oral Capps, and anonymous *Journal* reviewers for constructive comments on earlier drafts of this paper.

served production technology (as reflected in aggregate data) which is endogenous to the economic system (Mundlak and Hellinghausen, Mundlak).

In this paper, a simple model selection procedure is used to assess the likelihood support for a production model which does not restrict technical change to be invariant to changes in exogenous economic variables nor to stochastic shocks to the production system. Agricultural production behavior in the northeastern states region is analyzed using a primal behavioral model specification where technology is characterized by a generalized Fechner-Thurstone (GFT) functional form.[1] The GFT framework incorporates a parametric specification which maintains that optimization errors associated with changing technology can occur because of (*a*) stochastic variation of the production technology map, (*b*) alterations of the microproduction functions, and/or (*c*) choice among available production techniques.

Two classes of the GFT form are estimated using annual data for the period 1950–82. For each class three objectives are pursued: (*a*) Evaluate likelihood support for alternative serial correlation hypotheses on stochastic technology changers. (*b*) Evaluate the likelihood support for an empirical model of aggregate production embodied in the GFT specification of production technology relative to specific conventional production models which maintain invariance of technical change to changes in economic variables. (*c*) Evaluate both disembodied and embodied technical change hypotheses. In addition, Marshallian uncompensated factor demand elasticities are computed and analyzed for one class.

The Generalized Fechner-Thurstone Production System

Theoretical properties of GFT forms have been introduced and investigated by Basmann and by Basmann et al. (1983; 1984a, b; 1985; 1987). Additional contributions to the theoretical development of a GFT-class optimizing function in the context of production theory were presented in work by Charnes et al. (1976, 1983). Bewley and Young recently reported in th journal a GFT-class (generalized addilog) d mand system analysis of meat expenditures.

Motivation for our application of GFT-cla optimizing functions to aggregate regional a ricultural production technologies parallels many ways that of Basmann et al. (1983, 1984 1985). First, aggregate production behavior modeled within the context of the GFT fun tional class. The GFT is most general in the sen that any system of demand functions (which the result of some constrained optimization pr cess) can be derived by optimization of a fun tion defined within one of its classes. Oper tionally the GFT is a variable, random-coefficie generalized Cobb-Douglas functional form.

Second, aggregate production behavior modeled within a framework which does not r strict technical change to be invariant to chang in exogenous economic variables or stochast shocks to the production system. Price chang not only generate direct changes in chosen inp and output levels but also changes in the o served production function. The aggregate tec nology is a function of prices as well as oth state variables. Thus, as noted also by Mundla a correct interpretation of industry-level inp demand and output supply responses necess tates proper accounting for the endogenous n ture of the aggregate technology.

Third, the aggregate factor demand functio derived from the GFT production function ha the same form in arguments and parameters those derived from individual firm-level pr duction functions. Thus, the magnitude of t aggregate demand for any given factor is t arithmetic sum of magnitudes from the indivi ual producer demand functions (Basmann et a 1984a).

In addition, modeling the production tec nology in the GFT framework allows the eco omist to determine whether or not an accum lating body of evidence from observ equilibrium data supports the conventional m croeconomic assumption of independence b tween technical change and economic variable Rather than reproduce the properties of GF forms, the interested reader is directed to Ba mann et al. (1984a, b, 1985).

An Empirical Model

The aggregate production system for the nort eastern states region is modeled in a mann consistent with profit-maximizing price-taki

[1] This functional form was first proposed for indifference maps by L. L. Thurstone. In the special case of fixed technology, the GFT form reduces to a monotonically increasing function of the well-known Cobb-Douglas production function.

behavior subject to a budget constraint.[2] Assuming an aggregate output index, budget-constrained output maximization yields the same optimal solution as budget-constrained profit maximization. Let P be a vector of factor prices and let C denote expenditure on factors in a specified production period which is effectively constrained at C^*. Under the assumption that marginal products are positive for all factors, producers exhaust the aggregate budget in purchasing factors of production (i.e., $C = C^*$). It is assumed that producers select a definite equilibrium n-tuple production bundle $X = (x_1, \ldots, x_n)$ such that the choice results in maximization of a generalized Fechner-Thurstone production function for aggregate output:[3]

$$(1) \qquad F(X;\theta) = a\Pi_i x_i^{\theta_i(\gamma)},$$

subject to

$$(2) \qquad C = \Sigma_i p_i x_i,$$

where the n-tuple θ of positive-valued functions, $\theta_i(\gamma)$ $i = 1, \ldots, n$, is the parameter vector of $F(X;\theta)$.[4] For constant γ, the GFT production function is homogenous of degree $\Sigma_i\theta_i$, strongly separable and homothetic in X, and exhibits constant elasticity of substitution among elements of X equal to unity everywhere.[5]

In terms of economic behavior, elements of the argument vector X are under the producer's control, whereas elements of the parameter vector $\theta(\gamma)$ are not. The components of γ are referred to as technology changers. These are classified as (*a*) technology changers that are systematic and observable, and (*b*) technology changers that are stochastic and nonobservable. It is assumed that the marginal products derived from $F(X;\theta)$ can be expressed as a product of a systematic function and a stochastic element. A component γ_k of γ is said to be a technology changer with respect to $F(X;\theta)$ if, and only if, (*a*) the economic agent cannot quickly adjust γ_k to its optimal level when the exogenous prices and/or budget constraint change, or (*b*) a change in γ_k causes a change in at least one marginal rate of technical substitution for at least one point X_0 in the domain of $F(X;\theta)$.[6]

Family labor illustrates a systematic parameter in the vector γ. Few off-farm work opportunities are prevalent in many rural areas. Thus, family farm labor tends to adjust slowly toward optimal levels (e.g., Tweeten, pp. 175–76; Vasavada and Chambers). In addition, births and deaths may affect the slopes and shapes of the technology map of $F(X;\theta)$ by altering the composition of family farm laborers. Any variable that affects the production technology map in similar ways is called a technology changer.

A necessary consequence of budget-constrained output maximization is that the first partials of the following lagrangian with respect to variable inputs and the Lagrange multiplier equal zero:

$$(3) \qquad L = a\Pi_i x_i^{\theta_i(\gamma)} + \lambda(C - \Sigma_i p_i x_i),$$

where λ is the Lagrange multiplier. The $n + 1$ first-order conditions are

$$(4) \qquad \partial L/\partial x_i = \theta_i(\gamma)F(X;\theta)/x_i - \lambda p_i = 0, \quad i = 1, \ldots, n,$$

$$(5) \qquad \partial L/\partial \lambda = C - \Sigma_i p_i x_i = 0.$$

From (4)

$$(6) \qquad p_i x_i / p_j x_j \equiv S_i/S_j = \theta_i(\gamma)/\theta_j(\gamma),$$

where S_i is the ith input's share of cost. Note that, in equilibrium, the ratio of expenditures on factor i to factor j is equal to the ratio of GFT parameters. Solving (6) for p_i,

$$(7) \qquad p_i = [\theta_i(\gamma)/\theta_j(\gamma)]p_j x_j x_i,$$

and inserting (7) into (5) yields

$$(8) \qquad C = \Sigma_i[\theta_i(\gamma)/\theta_j(\gamma)](p_j x_j/x_i)/x_i = [p_j x_j/\theta_j(\gamma)]\Sigma_i\theta_i(\gamma).$$

Solving (8) for x_j yields the expenditure-constant factor demand functions,

[2] Farm lenders determine creditworthiness of individual borrowers based largely on expectations for repayment. These expectations can be expressed in the form of leverage limitations and/or borrower controls as well as interest rates. The combination of these manifestations suggests an aggregate limit on credit availability. In support of this maintained hypothesis, it is noted that an empirical test of budget-constrained profit maximization in U.S. agriculture was not rejected by Lee and Chambers for the period 1947–80. Unconstrained profit maximization, however, was rejected.

[3] This form is a special case of the one used by Basmann et al. (1984b), that restricts the origin of reference for the production function to (0, ..., 0). This function is also a special case of the generalized power production function (de Janvry), $F = a\Pi_i x_i^{\theta_i} e^{g(X)}$, with $g(X) = 0$ and generalized such that θ_i is a function of technology changers γ.

[4] The notational device of separating the arguments of a function from its parameters by a semicolon will be invoked throughout this paper.

[5] Since γ varies across time periods, these properties, which are implied by a Cobb-Douglas production function, hold only within a single production period. Thus, they are temporally local properties.

[6] By this definition of a technology changer, homothetic shifts in the technology map (i.e., neutral technical changes) are indistinguishable from no shift in the technology map. While this omission may appear important, empirical tests of technical change in U.S. agriculture have quite consistently found it to be non-neutral (e.g., see Antle 1984, Binswanger, Weaver).

(9) $$x_j = [\theta_j(\gamma)/\theta(\gamma)]C/p_j,$$

where $\theta(\gamma) = \Sigma_i\theta_i(\gamma)$.

Factor demand functions (9) depend only on the parameters of the specified GFT production function, $F(X;\theta)$, and the parameters of the budget constraint (2). Demand functions are homogenous of degree zero when elements of the technology changer vector γ are independent of budget constraint parameters. However, if changes in budget constraint parameters influence the shape of the technology map (as permitted in the empirical application), zero homogeneity is not implied. Generalization of GFT-rationalized demand systems is easily observed by noting that demand functions (9) have the form of the generalized demand system investigated by Seo. Because every system of demand functions which satisfies the ordinary linear budget constraint can be represented in the generalized form (Seo), it follows that every system of demand functions can be rationalized by some GFT-class function (Basmann et al. 1985, pp. 19–20).

Two GFT classes of production functions are investigated in this paper. Both are variations of the Cobb-Douglas functional form with variable, random coefficients. The first is the constant elasticity of marginal rate of technical substitution form (GFT-CEMRTS), and the second is the constant ratio of elasticity of substitution form (GFT-CRES). These classes were chosen for several reasons: (*a*) they provide a framework in which likelihood support among alternative serial correlation hypotheses on stochastic technology changers is easily investigated; (*b*) they permit easy evaluation of likelihood support for a model of technical change which is not based solely on information contained in parameters of time trend variables; (*c*) they do not impose arbitrary restrictions on the demand system at a point; (*d*) they provide an empirical framework for assessing the likelihood support for an endogenous technical change model relative to established conventional cases of production functions which have technology images within the respective GFT classes;[7] and (*e*) they permit evaluation of Hicksian technical bias and factor demand elasticities within the conte of a theoretical model where systematic and stc chastic technical change is allowed to warp th technology map.

[7] Maximum likelihood methods necessitate the complete specification of a parent population sample density function. Even if the stochastic element in the parameter vector $\theta(\gamma)$ is normally distributed, it is not practical to treat the whole class of parent populations as a grand maintained hypothesis. We have therefore chosen to assess subclasses of the whole GFT-class sequentially. Initially, we have focused on two maintained hypotheses that permit likelihood ratio tests of some widely recognized forms of conventional production functions.

GFT-CEMRTS Form

The GFT-CEMRTS form specifies that the $\theta($ parameters of (1) are characterized as follows

(10) $$\theta_i^*(C, P, Z) = \beta_i C^{w_{io}} \Pi_j p_j^{w_{ij}} \Pi_q z_q^{w_{iq}}, \quad i, j = 1, \ldots, n;\ q = 1, \ldots, m$$

(11) $$\theta_i = \theta_i^* e^{u_i},\ i = 1, \ldots, n,$$

where $u = \{u_1, \ldots, u_n\}$ is a latent random vectc with a mean of zero and a finite positive definit variance matrix, Ω_o. The vector u characterize a vector of stochastic technology changers. I addition, the serial covariance matrices Ω_s, $s =$ 1, 2, ..., n, may represent persistence of effect of stochastic changes in technology. The vectc Z characterizes systematic technology changer which are not parameters of the expenditur constraint and may include demographic infoi mation, weather variables, lagged values of and P, and other exogenous variables.

The estimation equations for the empirica model are characterized by

(12) $$\theta_i/\theta_k \equiv S_i/S_k = \beta_i C^{w_{io}} \Pi_j p_j^{w_{ij}} \Pi_q z_q^{w_{iq}} e^{u_i} / \beta_k C^{w_{ko}} \Pi_j p_j^{w_{kj}} \Pi_q z_q^{w_{kq}} e^{u_k}$$

Taking natural logarithms of (12) yields the − 1 estimation equations for the GFT-CEMRT model.

(13) $$\ln(S_i/S_k) = \ln(\beta_i/\beta_k) + w_{io}^k\ln(C) + \Sigma_j w_{ij}^k \ln(p_j) + \Sigma_q w_{iq}^k \ln(z_q) + \xi_i^k,\ i = 1, \ldots, n,\ i \neq k,$$

where $w_{io}^k = w_{io} - w_{ko}$, $w_{ij}^k = w_{ij} - w_{kj}$, $w_{iq}^k =$ $w_{iq} - w_{kq}$, and $\xi_i^k = u_i - u_k$.

Marshallian uncompensated factor deman elasticities with respect to changes in prices P the expenditure constraint C, and technolog changers Z are of the following form.

Price elasticity:

(14) $$\epsilon_{ij} = \Sigma_k(\theta_k/\theta)w_{ij}^k - \delta_{ij},$$

where

(15) $$\delta_{ij} = \begin{cases} 1 & \text{for } i = j, \\ 0 & \text{otherwise.} \end{cases}$$

Expenditure elasticity:

(16) $$\epsilon_{io} = \Sigma_k(\theta_k/\theta)w_{io}^k + 1.$$

Elasticity of factor demand with respect to a change is an element of the systematic technology changer, z_q:

$$(17) \qquad \epsilon_{iq} = \Sigma_k(\theta_k/\theta)w^k_{iq}.$$

The GFT model provides straightforward primal-based measurements of technical change biases. The estimated parameters measure the sensitivity of the slope of the isoquant to changes in technology changers at a given point on the aggregate expansion path.[8] That is, the elasticities of the marginal rates of technical substitution of factor k for factor i, with respect to expenditure (C), prices (P), and other systematic technology changers, (Z), are represented by the estimated parameters w^k_{io}, w^k_{ij}, w^k_{iq}, respectively, at a point in input space.

GFT-CRES Form

The GFT-CRES form specifies that the $\theta(\gamma)$ parameters of (1) are characterized as follows:

$$(18) \qquad \theta^*_i(C, P, Z) = \beta_i \Pi_j [x^*_j(C, P, Z)]^{b_{ij}} \Pi_q z_q^{b_{iq}}, \quad i, j = 1, \ldots, n; q = 1, \ldots, m,$$

$$(19) \qquad \theta_i = \theta^*_i e^{u_i}.$$

In equilibrium, $x_j = x^*_j(C, P, Z), j = 1, \ldots, n$, which are unknown functions. Since θ^*_i is functionally dependent only on (C, P, Z), satisfaction of the first-order conditions implies estimation equations characterized by

$$(20) \qquad \theta_i/\theta_k \equiv S_i/S_k = (\beta_i/\beta_k)\Pi_j(x_j)^{b_{ij}-b_{kj}}\pi_q z_q^{b_{iq}-b_{kq}} e^{u_i-u_k}.$$

Taking logarithms of (20) yields the $n-1$ estimation equations for the GFT-CRES model.

$$(21) \qquad \ln(S_i/S_k) = \ln(\beta_i/\beta_k) + \Sigma_j b^k_{ij}\ln(x_j) + \Sigma_q b^k_{iq}\ln(z_q) + \xi^k_i, \; i = 1, \ldots, n, \; i \neq k,$$

where $b^k_{ij} = b_{ij} - b_{kj}$, $b^k_{iq} = b_{iq} - b_{kq}$, and $\xi^k_i = u_i - u_k$.

As with the GFT-CEMRTS form, these estimated parameters provide a primal measure of bias in technical change. However, explicit forms of the GFT-CRES demand functions are not tractable. Therefore, demand elasticities for this class are not calculated.

Econometric Estimation

The stochastic variables, u_i, are assumed to affect demand functions (9) solely through the parameters $\theta(\gamma)$. Consequently, random variables are not "tacked-on" to demand functions. These errors in the estimation equations are caused by stochastic changes in technology not anticipated by decision makers rather than to errors in optimizing behavior. However, the equations estimated are not perfect fits of the actual optimizing behavior because of the presence of unobserved causal variables which change over the data period and to measurement errors on observed variables.

For this study each of the random elements ξ^k_i given in equations (13) and (21) is assumed to follow a second-order autoregressive schema. The random element ξ^k_i in each estimation equation takes the form.

$$(22) \qquad \xi^k_{i,t+2} - \Phi_{i,1}\xi^k_{i,t+1} + \Phi_{i,2}\xi^k_{i,t} = \epsilon_{i,t+2}, \forall i, k,$$

where $E[\epsilon_t] = 0$, $E[\epsilon_t\epsilon_s] = 0$ for $t \neq s$, and $E[\epsilon^2_t] = \sigma^2_\epsilon$.

Basmann's theory on the serial correlation of stochastic taste changes modeled in the context of GFT forms provides a methodology for reducing the number of independent parameters associated with estimation of an autoregressive production system. For a second-order autoregressive schema, the autocovariance matrices are determined by the variance matrix and the two AR(2) autocorrelation coefficients, $\Phi_{i,1}$ and $\Phi_{i,2}$. Minimal sufficient statistics for each empirical model were estimated using the general linear model (GLM).[9] The dependent variable vector and the matrix of independent variables were transformed according to a maintained AR(2) hypothesis on $\Phi_{i,1}$ and $\Phi_{i,2}$ values over the stability domain implied by the Routhian conditions (Kenkle). The GLS estimators were then obtained by applying the method of least squares to the transformed model (Judge et al.). For restricted models with cross-equation restrictions and/or where the regressors were not the same in all equations, i.e., (24)–(30), the seemingly unrelated (SUR) estimation procedure (Zellner)

[8] Note from (6) and (13) that $w^k_{i,time}$, which equals $\partial\ln(F_i/F_k)/\partial\ln(time)$ in equilibrium, provides an equivalent qualitative measure of the technical change bias parameter B_{ik} presented by Antle and Capalbo in their equation (13) in chapter 2. The technical bias with respect to any of the exogenous variables can be computed in like manner (Antle 1988) from the estimated parameters.

[9] The minimal sufficient statistics are the parameter estimates and the variance-covariance matrix associated with the estimated model (Mood, Graybill, and Boes).

was employed to obtain parameter estimates for the system.

Data

Each model was estimated using annual agricultural production data for the northeastern states rėgion which includes the eleven states Connecticut, Delaware, Massachusetts, Maryland, Maine, New Hampshire, New Jersey, New York, Pennsylvania, Rhode Island, and Vermont. The data were constructed by Fawson and Gottret and represent a comprehensive divisia index characterization of both prices and quantities of production aggregates from 1950 to 1982. Variables included prices (P) and quantities (X) of six variable factors: hired labor, machinery, energy, fertilizer and pesticides (chemicals), marketing and processing services for feed, seed, and livestock (FSL), and other materials. They also included total expenditure on these variable factors (C) and seven systematic technology changers (Z): year, real estate quantity, family labor quantity, sample standard deviation of monthly average temperatures over the year, sample mean of monthly average temperatures for the year, sample standard deviation of monthly precipitation over the year, and sample mean of monthly precipitation for the year. Using these data, a five-equation system, (13) or (21), was estimated for each GFT-class model investigated with materials designated as the *numèraire* factor.[10] With a single output index and a binding budget constraint, the optimal solution is not dependent on output price. Thus, output price does not appear as one of the exogenous price variables in the estimation equations.

Empirical Results

In this section, likelihood ratio tests (Mood, Graybill, and Boes; Graybill) are conducted and reported: first, to determine likelihood support for alternative serial correlation hypotheses on stochastic technology changers; second, to investigate disembodied and embodied technical change hypotheses; and third, to evaluate the likelihood support for an endogenous technical change model embodied in the GFT specification relative to the case in which technical change is maintained invariant to changes in economic variables. The testing procedure is based on evaluation of the likelihood support for the minimal sufficient statistics associated with a given model specification. Hicksian technical bias is investigated by computing primal cost-share-weighted summary measures of the sensitivity of marginal rates of technical substitution to changes in technology changing variables. Marshallian uncompensated factor demand elasticities (Lee and Chambers, p. 864) are then computed, and mean values of the distribution of elasticities are reported and analyzed for the GFT-CEMRTS model.

Determination of Serial Correlation

A grid search method was utilized to evaluate the likelihood support for 138 two-tuple sets of autocorrelation parameters $\Phi_{i,1}$ and $\Phi_{i,2}$ specified to provide extensive coverage within the stability triangle of a second-order autoregressive schema. The likelihood support for a given AR(2) hypothesis within a model class was assessed by examining the ratio of the likelihood function for a specific AR(2) two-tuple hypothesis set relative to the maximum value of the likelihood function over all 138 AR(2) two-tuple hypothesis sets which were specified. A three-dimensional graph of the relative likelihood support is presented in figure 1 for the GFT-CEMRTS class and in figure 2 for the GFT-CRES class, where Φ_1^*, Φ_2^* denotes the AR(2) parameters which generated the maximum likelihood support over the stability region. Examination of the figures reveals little likelihood support for the hypothesis of zero serial correlation.

Subsequent hypothesis testing was limited to those AR(2) hypotheses for which the value of the likelihood function (given the maintained hypotheses about the AR(2) process) was within 70% of the maximum value of the likelihood function evaluated over the population of 138 two-tuple AR(2) hypothesis sets. For the GFT-CEMRTS class, this heuristic indicated seventeen AR(2) hypotheses which would be used for subsequent tests with the maximum value of the likelihood function at $\Phi_1 = -0.40$ and $\Phi_2 = 0.90$. For the GFT-CRES model, we considered a set of ten AR(2) hypotheses for further investigation with the maximum value of the likelihood function occurring at $\Phi_1 = 0.00$ and $\Phi_2 =$

[10] Real estate and family labor could appropriately be regarded as decision variables. However, good price series are not available for either input in this region, they are frequently regarded as quasi-fixed inputs in economic analysis, and they also affect choice among microproduction processes. Consequently, they are included along with weather variables and year as systematic technology changers.

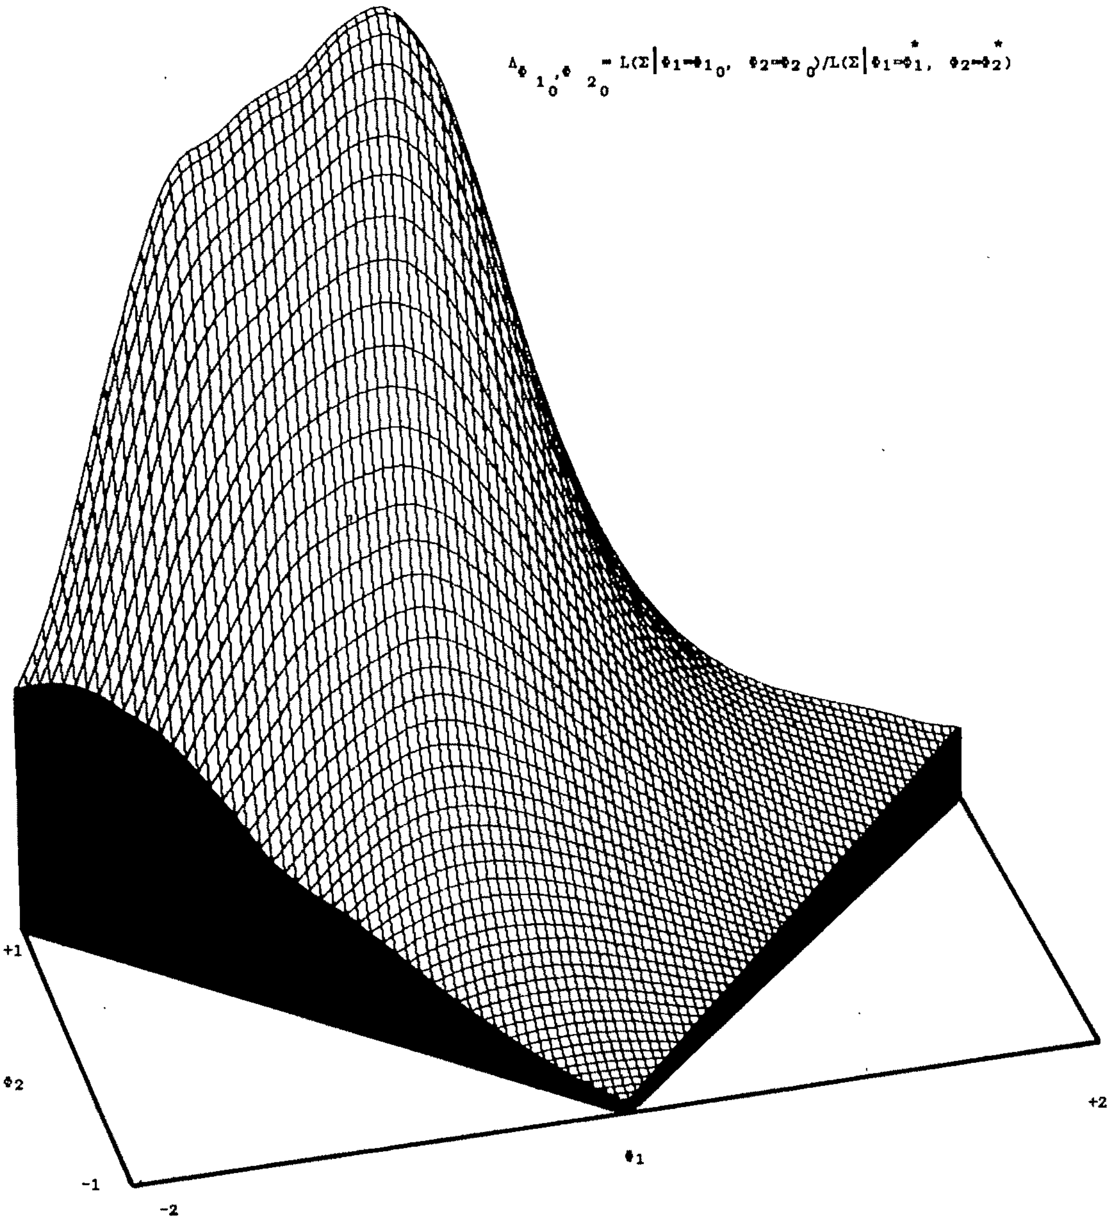

Figure 1. Likelihood ratio support for AR(2) hypotheses within the GFT-CEMRTS class

0.90. Parameter estimates for equations evaluated at the maximum AR(2) hypothesis are presented in tables 1 and 2, respectively.

Model Specification (Technology Change) Tests

Several hypotheses restricting the set of systematic technology changers were tested to determine whether production can be modeled legitimately with a more parsimonious GFT-class functional form. Hypothesis tests between restricted and unrestricted models within the specified GFT class were performed using a likelihood ratio test statistic:

$$(23) \quad \lambda_{\Phi_1,\Phi_2} = L(\text{restricted under } H_0|\Phi_1 = \Phi_{1(0)}, \Phi_2 = \Phi_{2(0)})/L(\text{unrestricted}|\Phi_1 = \Phi_{1(0)}, \Phi_2 = \Phi_{2(0)}),$$

where $\Phi_{K(0)}$ is the maintained serial correlation parameter value. A generalized likelihood ratio

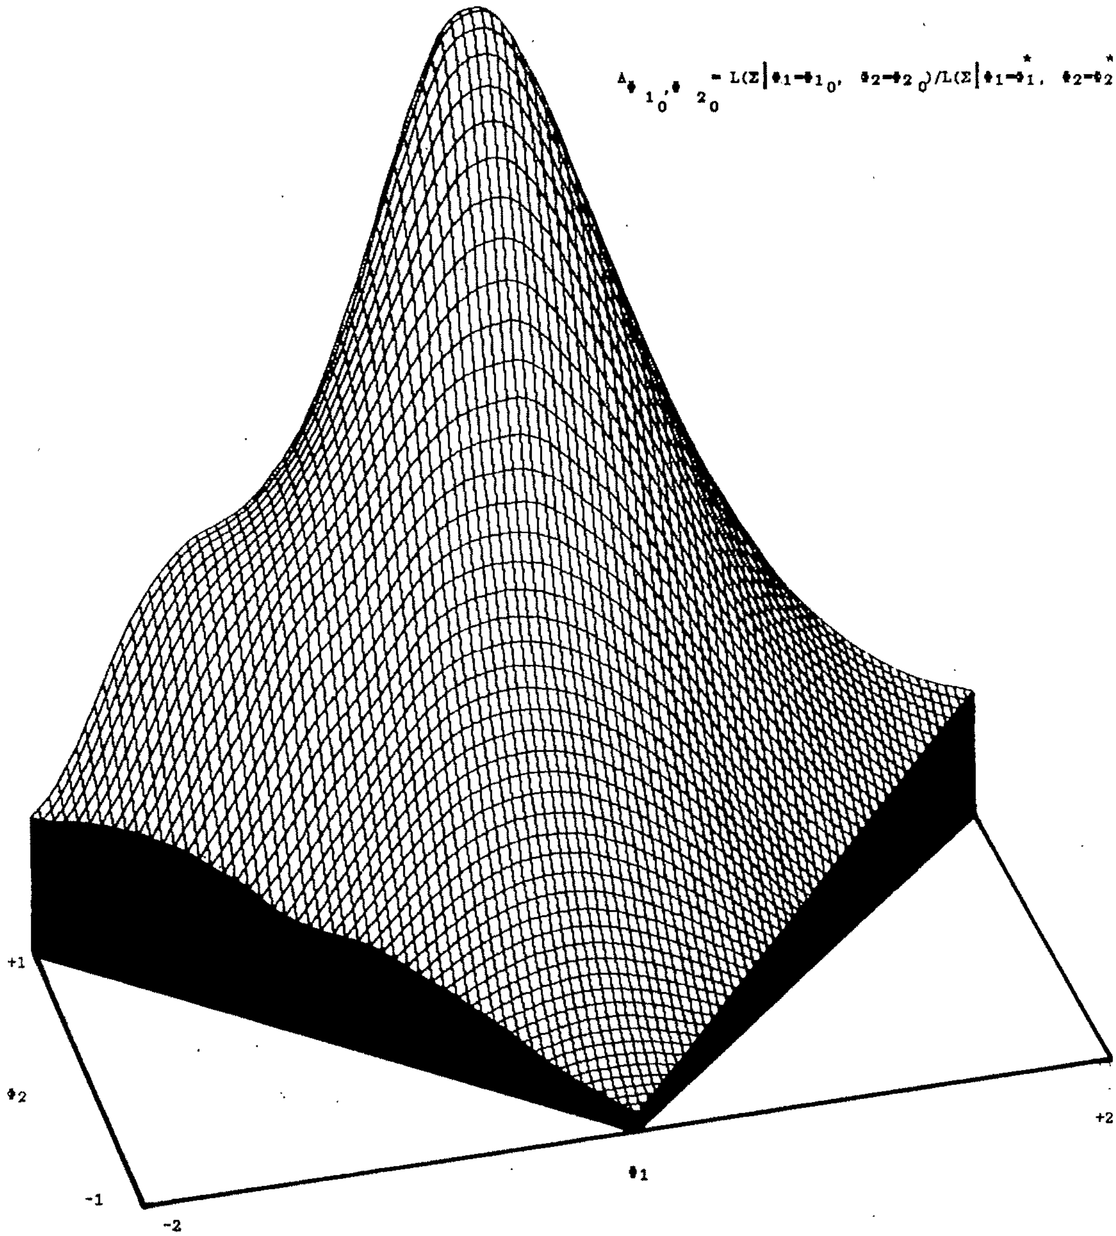

Figure 2. Likelihood ratio support for AR(2) hypotheses within the GFT-CRES class

test was defined as follows: Reject H_0 if, and only if, $-2\ \ln(\lambda_{\Phi_1,\Phi_2}) > \chi^2_{(1-\alpha)}(r)$, where $\chi^2_{(1-\alpha)}(r)$ is the $(1-\alpha)$ quantile of the chi-square distribution with r degrees of freedom. The critical bound was set to be the .95 quantile of the chi-square distribution.

Null hypotheses associated with the restricted models investigated for both GFT classes are presented in table 3. The associated likelihood ratio test statistics evaluated over the restricted set of AR(2) parameters are presented in table 4 for the GFT-CEMRTS class and in table 5 for the GFT-CRES class.

One of the important reasons for selecting a GFT-class function was to model technical progress without strict reliance on time trend variables. Likelihood ratio test statistics for the GFT-CEMRTS-class systematic technology tests indicated no support for eliminating the time trend variable or the standard deviation of the two weather variables as independent technical change variables in the production model. In addition

[a] Numbers in parentheses are *P*-values associated with a two-tailed *t*-test for the null hypothesis that the parameter is zero. The endogenous variable in each equation was the logarithm of the ratio of cost shares of the specified input and materials.

other systematic technology tests indicated no likelihood support for eliminating the set of systematic technology changers which are not parameters of the budget constraint or the set which are parameters of the budget constraint.

Likelihood ratio test statistics for hypotheses which restrict the set of systematic technology changers in the GFT-CRES class were consistent with those for the GFT-CEMRTS class. There was no likelihood support for eliminating the trend variable or the standard deviation of either weather variable. Neither was there likelihood support for eliminating the other sets of systematic technology changers.

Functional Form Tests

The ability of the GFT-class production function to provide a foundation for testing whether technical change is endogenous to the production system is based on the concept of observational equivalence between conventional production technologies and images of those technologies which are nested within a GFT class. This section establishes the foundation for empirical refutation of the conventional hypotheses by examining seven cases of production functions which express independence between technical change and economic variables associated with the budget constraint. These cases were chosen because of their historical importance in the applied literature and their simplicity in demonstrating the tests made possible within the GFT modeling framework. Although not presented here, more complex second-order functions which have production technology images nested within the GFT class can also be tested.

The alternative conventional functional specifications for the system of equations ($i = 1, \ldots, n$, $i \neq k$) which have technology images within the GFT-CEMRTS and GFT-CRES classes are as follows:

Table 2. Parameter Estimates for GFT-CRES System, $\Phi_1 = 0.00$, $\Phi_2 = 0.90$

[a] Approximate area in the upper tail of a chi-square distribution with r degrees of freedom are in parentheses.

Cobb-Douglas: (GFT-CEMRTS Class)

$$(24)\quad \ln(S_i/S_k) = \ln(\beta_i/\beta_k) + \Sigma_q w^k_{iq} \ln(z_q) + \xi^k_i.$$

Leontief: (GFT-CEMRTS Class)

$$(25)\quad \ln(S_i/S_k) = \ln(\beta_i/\beta_k) + w^k_{ii}\ln(p_i) + w^k_{ik}\ln(p_k) + \Sigma_q w^k_{iq}\ln(z_q) + \xi^k_i$$

with restrictions (i) $w^k_{ik} + w^k_{ii} = 0$, and (ii) $w^k_{ii} = 1$.

Relaxed CES: (GFT-CEMRTS Class)

$$(26)\quad \ln(S_i/S_k) = \ln(\beta_i/\beta_k) + w^k_{ii}\ln(p_i) + w^k_{ik}\ln(p_k) + \Sigma_q w^k_{iq}\ln(z_q) + \xi^k_i$$

with restrictions (i) $w^k_{ik} = w^k_{jk}$, $i, j = 1, \ldots, n, \neq k$.

CES: (GFT-CEMRTS Class)

$$(27)\quad \ln(S_i/S_k) = \ln(\beta_i/\beta_k) + w^k_{ii}\ln(p_i) + w^k_{ik}\ln(p_k) + \Sigma_q w^k_{iq}\ln(z_q) + \xi^k_i$$

with restrictions (i) $w^k_{ii} + w^k_{ik} = 0$.

Leser-Houthakker: (GFT-CEMRTS Class) (see Leser, Houthakker)

$$(28)\quad \ln(S_i/S_k) = \ln(\beta_i/\beta_k) + w^k_{io}\ln(C) + w^k_{ii}\ln(p_i) + w^k_{ik}\ln(p_k) + \Sigma_q w^k_{iq}\ln(z_q) + \xi^k_i$$

with restrictions (i) $w^k_{ik} = w^k_{jk}$ $i, j = 1, \ldots, n, \neq k$, ($ii$) $w^k_{io} + w^k_{ii} + w^k_{ik} = 0$, ($iii$) $w^k_{ii} < 1$, $w^k_{ik} > -1$.

Relaxed CRES: (GFT-CRES Class) (see Mukerji)

$$(29)\quad \ln(S_i/S_k) = \ln(\beta_i/\beta_k) + b^k_{ii}\ln(x_i) + b^k_{ik}\ln(x_k) + \Sigma_q b^k_{iq}\ln(z_q) + \xi^k_i.$$

Strict CRES: (GFT-CRES Class)

$$(30)\quad \ln(S_i/S_k) = \ln(\beta_i/\beta_k) + b^k_{ii}\ln(x_i) + b^k_{ik}\ln(x_k) + \Sigma_q b^k_{iq}\ln(z_q) + \xi^k_i$$

with restrictions (i) $b^k_{ik} = b^k_{jk}$ $i, j = 1, \ldots, n, \neq k$. The null hypotheses and degrees of freedom associated with these functional forms are presented in table 3.[11]

[11] The concept of a functional form having an image within a GFT class implies an observational equivalence between demand behavior modeled by the GFT form and its neoclassical counterpart which does not allow for the possibility of changes in the production technology map because of changes in exogenous economic variables. This is easily demonstrated by comparing the ratio of expenditure shares derived under a GFT-CEMRTS form with CES restrictions [see (27)] and its neoclassical counterpart defined by $F(X; \beta, \partial, \nu) = (\Sigma_i \beta_i x_i^{-\partial})^{-\nu/\partial}$. Because the GFT-class functions implied by equations (24) through (30) are images of their neoclassical counterparts, all properties which are maintained in the neoclassical specification with respect to homogeneity, separability, and elasticity of substitution are maintained in the observationally equivalent GFT specification.

Results of the likelihood ratio tests for restricted functional forms with images in the GFT-CEMRTS class are presented in table 4. The tests indicated no favorable support for any of these functional form specifications relative to the unrestricted GFT-CEMRTS model.[12] Results of the likelihood ratio tests for restricted functional forms with images in the GFT-CRES class are presented in table 5. These tests showed that CRES forms with neoclassical restrictions on the set of technology changers also have little likelihood support in the empirical data.

Likelihood ratio tests indicated that GFT-class forms perform well relative to these seven strict classical functional forms. This finding provides impetus for further investigation of GFT-class forms to assess the support for maintaining the strict classical criterion in analyzing aggregate production systems.

[12] The Cobb-Douglas form, equation (24), was not tested separately. It is a nested hypothesis of the CES form which was strongly rejected.

Technical Change Biases

Following the convention of Lau, Antle and Capalbo, and others, we define direct Hicks-neutral technical change as expansion-path-preserving technical change. As such, a primal measure of Hicksian bias in technical change would assess the sensitivity of marginal rates of technical substitution at a given point in input space to changes in technology changing instruments. Estimated parameters in (13) for the GFT-CEMRTS system and (21) for the GFT-CRES system are the elasticities of the marginal rates of technical substitution with respect to exogenous variables. Thus, they are measures of Hicksian bias. Following Antle (1988, p. 357) and Antle and Capalbo (pp. 38–39), primal cost-share-weighted summary measures of Hicksian bias for input i with respect to technology changer h were computed at given input levels as

$$(31)\quad B_{i,h}(X, \gamma_h) = \Sigma_j S_j\, \partial \ln(f_i/f_j)/\partial \ln \gamma_h,$$

where S_i is the ith input's cost share, f_i is $\partial \ln F/$

[a] Numbers in parentheses are the standard errors of the summary measures of Hicksian bias.

$\partial \ln x_i = \theta_i$, and γ_h is the hth exogenous variable. For the GFT-CEMRTS system,

$$B_{i,h}(X, \gamma_h) = \Sigma_j S_j w^j_{ih} = \Sigma_j S_j (w^k_{ih} - w^k_{jh}),$$

where k is the *numèraire* factor. For the GFT-CRES,

$$B_{i,h}(X, \gamma_h) = \Sigma_j S_j (b^k_{ih} - b^k_{jh}).$$

Equation (31) is qualitatively identical to Antle's (1988) and Antle and Capalbo's primal summary measures of Hicksian bias. For example, when technology changer γ_h is the trend variable, technical change is Hicks neutral, using, or saving with respect to time as $B_{i,h} = 0$, $B_{i,h} > 0$, or $B_{i,h} < 0$, respectively. The ith factor's relative marginal product is on average directly (inversely) related to variation in technology changer γ_h as $B_{i,h} > 0$ ($B_{i,h} < 0$). The summary measures of bias are reported at the data means in table 6 for the GFT-CEMRTS system estimates and in table 7 for the GFT-CRES system estimates.[13]

For the GFT-CEMRTS system, factor prices, budget, family labor, and mean precipitation generally have a significant (5% level) impact on relative marginal products. The two significant trend parameters suggest energy-saving and chemicals-using technical change over time.

In interpreting summary measures of Hicksian bias for the GFT-CRES system, it is useful to note that economic variables influence the technology map through the functions $x^*_j(C, P, Z)$, which are unknown. As a result, the influence of economic variables on technology choice is observed through factor utilization in equilibrium where $x_j = x^*_j(C, P, Z)$. We are unable to distinguish between price and budget effects for the GFT-CRES system as is possible for the GFT-CEMRTS system, but we can observe the combined influence of price and budget effects on the equilibrium factor usage choices. For the GFT-CRES system, hired labor, energy, chemicals, standard deviation of

[13] For the GFT-CEMRTS system, the parameter $w^j_{kk} = w_{kk} - w_{kk}$ takes on a value of zero, but its variance is not necessarily zero. Since the variance of w^j_{kk} is intractable, it is assumed to be zero when calculating the variance of the summary measures of Hicksian bias. As a result, the standard errors for summary measures of Hicksian bias represent lower bounds. The same is true for the GFT-CRES system summary measures of Hicksian bias.

[a] Numbers in parentheses are the standard errors of the summary measures of Hicksian bias.

temperature, and trend often have a significant impact on relative marginal products. Significant parameters for the trend variable suggest factor-using technical change over time for machinery, energy, chemicals, and materials and factor-saving technical change for the feed, seed, and livestock input category.

For elements of γ which are common to the two functional specifications, the only significant Hicksian summary measure that differs in sign is on the trend variable for energy. The GFT-CEMRTS model suggests that Hicks technical change is on average significantly energy saving, and the GFT-CRES model suggests that Hicks technical change is on average significantly energy using over time.

In interpreting the Hicksian summary measures, the suggestion that these measures are indicative of induced technical change has been avoided. The induced technical change hypothesis implies a causal temporal relationship. We have not included expectations of technical change, either through dynamic modeling (e.g., Antle 1988) or through factor augmentation instruments (Kawagoe, Otsuka, and Hayami) in this study. As a result technical change cannot be interpreted as induced. However, the GFT modeling framework does not limit one a priori to Hicksian-bias technical analysis; for example, factor augmentation instruments and lagged economic variables could be included in the vector of technical changer variables, γ, to investigate induced bias.

Estimated Elasticities

Factor demand elasticities were evaluated at GFT-CEMRTS parameter estimate values associated with the AR(2) hypothesis which generated the largest likelihood support over the stability region. The mean value and standard deviation of computed Marshallian uncompensated factor demand elasticities are reported in table 8.

With the exception of the hired labor factor, all own-price elasticities were negative, and all

[a] Numbers in parentheses are the standard deviations of the distributions of elasticity values.

elasticities with respect to the expenditure constraint C were positive. The mean own-price elasticity for hired labor is not significantly different from zero. This finding is consistent with recent work by Shumway and Alexander for this region. The sluggish adjustment of hired labor toward its optimal level is also consistent with recent estimates by Baffes and Vasavada for the U.S. agricultural sector. Given the large decrease in hired labor usage over the sample period, its negative elasticity with respect to the expenditure constraint is perhaps not surprising.

Mean elasticities indicate that usage of energy, materials, and feed, seed, and livestock marketing services are substitutes for (i.e., inversely related to) family labor. In addition, usage of machinery, energy, and feed, seed, and livestock marketing services are substitutes for real estate. Other variable inputs are complements to family labor and real estate. Factor demand elasticities with respect to the real estate and family labor variables indicate that changes in these variables elicit important changes in the mix of the factor bundle. Elasticities with respect to weather variables suggest that factor demand is more sensitive to temperature than precipitation, and more sensitive to mean changes than deviations from the mean. Although hypothesis tests fail to reject the significance of a trend variable, factor demands are relatively unresponsive to year.

Of thirty cross-price relationships among variable inputs, nineteen are complements and eleven are substitutes. Because the price elasticities of demand are the expenditure-constant profit maximization (Marshallian uncompensated) variety rather than output-constant cost-minimization (Hicksian) or unconstrained profit-maximization (Marshallian) elasticities, the symmetry property of the cross-partial derivatives does not imply symmetry in signs of the cross-price elasticities. In fact, signs for five of the fifteen pairs of cross-price elasticities differ.

Compared to prior elasticity estimates for this region (Gempesaw and Dunn, Shumway and Alexander), the absolute magnitudes of these estimates tend to be higher for both own-price and cross-price relationships. Both prior sets of estimates were compensated Marshallian elasticities obtained under the assumptions of zero serial correlation, a strict neoclassical production technology, and technology change invariant to changes in economic variables. Although signs and magnitudes of specific elasticities differ from the prior estimates, there is strong evidence from all the studies of both complements and substitutes among pairs of inputs.

Unlike the previous studies, homogeneity of degree zero of the factor demand equations is not a maintained hypothesis in this model. Changes in budget constraint parameters do influence the shape of the technology map giving sums of elasticities (at the means) with respect to input prices and cost ranging from $-.413$ for materials to .629 for hired labor. For only two inputs (feed, seed, and livestock marketing services and machinery), do proportionate changes in input prices and the cost constraint have little impact on the quantity of the input demanded.

Conclusions

This research has focused on empirical characterization of technological relationships among factors in aggregate agricultural production processes. The generalized Fechner-Thurstone functional specification was employed to relax strict neoclassical efficiency constraints and to provide a means for modeling systematic and stochastic technical change without exclusive reliance on time trend variables.

Two GFT-class models were specified under a second-order autoregressive schema: The constant elasticity of marginal rate of technical substitution model (GFT-CEMRTS), and the constant ratio of elasticity of substitution model (GFT-CRES). Each GFT-class model was tested against commonly maintained technical change hypotheses as well as classical functional forms having technology images nested within their class. Likelihood ratio tests indicated strong support for rejection of both the simplified technical change specifications and the classical functional forms relative to their unrestricted GFT-class counterparts.

Summary measures of Hicksian bias suggested that changes in economic variables exhibit a significant systematic effect on the shape of regional agricultural production technology. Both models found that temporal technical change was significantly chemicals using, but they rendered conflicting conclusions about the bias for energy. The GFT-CRES model also suggested that temporal technical change was significantly factor using for machinery and materials and factor saving for the feed, seed, and livestock input category.

All GFT-CEMRTS own-price Marshallian uncompensated factor demand elasticities were negative or not significantly positive. Five of the six demand elasticities with respect to cost were

positive. Because changes in the budget constraint parameters influenced the shape of the technology map, input demand equations were not homogenous of degree zero. Elasticities suggest a proportionate increase in all variable input prices and the cost constraint would substantially increase the demand for hired labor, energy, and chemicals and decrease the demand for materials.

Approximately two-thirds of the pairs of variable input demand relationships were complementary. Half of the variable inputs were complements to each of the fixed inputs (real estate and family labor) and half were substitutes. Relatively large cross-price elasticities were evident for several of the inputs. The estimates clearly document the fundamental and powerful impact on input demands and particularly on input combinations of federal agricultural policy that has frequently sought to alter the quantity of land used in production.

Input Allocation in Multicrop Systems

Richard E. Just, David Zilberman, Eithan Hochman, and Ziv Bar-Shira

Using data only on aggregate variable input use and land allocation, this paper suggests a methodology for allocating variable input use among crops and improvement of regional crop budget information. Two approaches for estimation of variable input allocations among production activities are examined. One relies on behavioral rules whereby input allocations follow accepted rules of thumb. The alternative approach is derived from profit maximization where input use responds instantaneously to changes in input and output prices. The behavioral rules dominate instantaneous response to prices in explaining the data analyzed in this paper and suggest the validity of a simple behavioral approach for developing enterprise budgets and cost of production estimates.

Key words: behavioral rules, enterprise budgets, profit maximization, variable input allocation.

A major responsibility of farm management economists is to develop reliable crop budgets. Too often crop budgets are developed by guesstimates based on only a handful of informal interviews rather than formal statistical analysis.[1] Also, since 1973 the U.S. Secretary of Agriculture has been legislatively mandated to conduct national cost of production studies for selected crops. Because most farms produce several crops and do not record input use by crop, producing reliable crop budgets and enterprise cost of production estimates requires sound estimation of variable input allocations among crops (Hornbaker, Dixon, and Sonka).

One approach is to survey farmers, asking them to estimate the amounts of each input they allocate to each crop. Because of survey cost considerations, this approach has been feasible only infrequently.[2] Another approach is to use data on total farm inputs by category to develop systematic estimates of use per acre by crop. Formal methodologies for estimating variable input allocations have not been developed until recently (Shumway, Pope, and Nash; Just, Zilberman, and Hochman). Cost of survey considerations have lead Baum et al. to propose the use of systematic procedures for allocating total farm input use among crops as a means of improving the quality of cost of production estimates.

One purpose of this paper is to suggest a simple procedure for estimating these allocations. The procedure considers a typical pattern of farm-level data availability (e.g., as with many computerized farm record-keeping systems). The estimated relationship describes farmer behavior in the traditional paradigm under which crop budgets are strictly appropriate (e.g., linear programming as it was applied historically). Specifically, farmers are supposed to behave as if their production functions follow constant returns to scale with fixed input/land ratios. These ratios are assumed to be based on regional av-

Richard E. Just is a professor of agricultural and resource economics, University of Maryland; David Zilberman is a professor of agricultural and resource economics, University of California, Berkeley; Eithan Hochman is a professor of Economics, Ben Gurion University of the Negev, Beer Sheva; and Ziv Bar-Shira is a graduate student, University of California, Berkeley.

This research was partly supported by the Phillip Monaster Institute, Ben Gurion University of the Negev. The research was part of BARD project no. US-1161-86R.

[1] A typical statement of methodology in an extension farm management budget publication is, "The following data are composite figures gathered from a representative group of . . . growers." (This statement appears in a California county extension publication but appears sufficiently typical that no one such publication should be singled out.)

[2] For example, the USDA Cost and Returns Survey attempts only to identify input use by crop for one crop each year with the chosen crop changing from year to year. By comparison, data on total farm inputs by input category is collected every year along with acreage and production by crop.

erages with modifications for seasonal and farm-specific conditions. Necessary data include only records on land allocation by crop (or an alternative measure of activity level for livestock), total purchases by input, and total sales by output.

Typical criticisms of crop budgets are their implicit assumption of fixed proportions production and lack of information on appropriate input-use response to changes in prices. A second purpose of this paper is to provide a test for the validity of this fixed proportions assumption in reflecting farmer behavior. Two approaches for estimation of variable input allocations among activities are examined. One relies on behavioral rules whereby input allocations (input/land ratios) follow accepted practices. The alternative approach is derived from the traditional profit maximization paradigm, where input use responds instantaneously to changes in input and output prices. The former dominates the latter statistically in the empirical case of this paper and suggests the validity of a simple behavioral approach for developing enterprise budgets and cost-of-production estimates.

Allocation of Inputs Among Crops: A Behavioral Approach

The behavioral approach of this paper describes variable input allocation in a region with a group of I farmers ($i = 1, 2, \ldots, I$) producing K crops ($k = 1, 2, \ldots, K$) using J inputs ($j = 1, 2, \ldots, J$) over a period of T years ($t = 1, 2, \ldots, T$).[3] The statistical analysis consists of estimating the allocation of variable inputs among crops. The two items of information used for these estimations are L_{kit}, which is the area allocated by individual i to the production of crop k at time t; and X_{jit}, which is the aggregate quantity of input j used by individual i at time t. Obviously,

$$(1) \qquad X_{jit} = \sum_{k=1}^{K} X_{kjit},$$

where X_{kjit} is the unobserved quantity of input j allocated by individual i at time t to production of crop k.

Information on X_{jit} is likely to exist for many farms because most bookkeeping and accounting systems register transactions between the farmer and other agents. However, internal transactions that allocate inputs among activities are rarely recorded. Land allocation data are more likely to exist than data on allocation of variable inputs. Land allocation is easily measured and is the main element of farmers' production plans (Hornbaker, Dixon, and Sonka).

The estimated relationships of the allocation of variable inputs among crops are derived from assumptions about the rules which characterize farmer behavior. Farmers are assumed to act as though their production functions have constant returns to scale. Hence, their decisions consist of the variable input/land ratios and land allocations. Following Rogers, Schultz, and others, farmers are assumed to exchange information in assessing technologies and markets and to imitate one another. They also receive essentially the same information from extension sources and the media. While imitation and similar information lead to uniformity in behavior, differences in farm and farmer characteristics lead to systematic variations among individuals. This permits input/land ratio decisions to be characterized by an overall average level, an annual deviation reflecting economic and weather variations and a systematic farmer deviation reflecting land quality, human ability, and perceptions.[4]

Let $x_{kjit} = X_{kjit}/L_{kit}$ be the quantity of input j per unit of land used at time t by farmer i in producing crop k. Then the systematic element of x_{kjit} denoted by x^*_{kjit} can be decomposed following

$$(2) \qquad x^*_{kjit} = \alpha_{kj} + \beta_{ji} + \gamma_{jt},$$

where α_{kj} is an average regional use of variable input j per unit of land in the production of crop k throughout the period of analysis, γ_{jt} denotes deviations from the regional average for use of input j at time t, and β_{ji} denotes deviations by farmer i from the regional average for use of input j. Using (1) and (2), the components of x^*_{kjit} can be estimated following

$$(3) \qquad X_{jit} = \sum_{k=1}^{K} [\alpha_{kj} + \beta_{ji} + \gamma_{jt}]\, L_{kit} + \epsilon_{jit},$$

where ϵ_{jit} is a random deviation associated with farmer i and input j at time t. For empirical pur-

[3] Here we assume that a crop uses a uniform technology on all land allocated to that crop. If more than one technology is used in producing a crop (e.g., irrigation and nonirrigation), then the methodology carries through if crops are defined by crop-technology combinations.

[4] Baum et al.'s suggestion for variable input allocation is a special case of this approach with no farmer or time differences (their sample had only one time period).

poses, ϵ_{jit} is assumed to be normally and independently distributed.[5]

Estimation of equation (3) requires regressing total use of each variable input on the acreages allocated to each of the crops crossed with dummy variables. The dummy variables correspond to the crop effect, farmer effect, and time effect. The sum of the estimated parameters $\hat{\alpha}_{kj} + \hat{\beta}_{ji} + \hat{\gamma}_{jt}$, is an estimate of the per acre allocation of variable input j to crop k by farmer i at time t. Multiplication of this estimate by the land allocated to the crop results in the behavioral estimate of the allocation of variable input j to crop k at time t,

$$(4) \qquad \hat{X}^b_{kjit} = [\hat{\alpha}_{kj} + \hat{\beta}_{ji} + \hat{\gamma}_{jt}]\, L_{kit},$$

where the superscript b denotes the behavioral model.

A Profit Maximization Approach to Allocation of Inputs

This section outlines a profit maximization approach which parallels the structure and data requirements of the behavioral approach. To obtain an estimable relationship describing variable input allocation, note that the short-run profit maximization problem of the firm is

$$(5) \qquad \max_{X_{kjit}} \sum_{k=1}^{K} P_{kt}\, Q_{kit} - \sum_{j=1}^{J} W_{jt}\, X_{jit},$$

$$\text{s.t. } Q_{kit} = f_{kit}(X_{k1it}, X_{k2it}, X_{k2it}, \ldots, X_{kJit}, L_{kit}), \quad k = 1, 2, \ldots, K,$$

$$X_{jit} = \sum_{k=1}^{K} X_{kjit}$$

where P_{kt} is the price of output k at time t, W_{jt} is the price of input j at time t, and f_{kit} is the production function of farmer i for output k at time t. The first-order conditions determining variable input use for (5) are

$$W_{jt} = P_{kt} \frac{\partial f_{kit}}{\partial X_{kjit}}, \; k = 1, \ldots, K; j = 1, \ldots, J.$$

Using elasticities, these conditions become

$$(6) \qquad X_{kjit} = \frac{R_{kit}}{W_{jt}} e_{kjit},$$

where $e_{kjit} = (\partial f_{kit}/\partial X_{kjit})\,(X_{kjit}/Q_{kit})$ is the elasticity of input j in production of output k by farmer i at time t and R_{kit} is revenue from sales of good k by farmer i at time t.

The e_{kjit} are elasticities at the optimal solution. They are not assumed to be constant and hence their use does not imply Cobb-Douglas production. Suppose they vary among farmers, among crops, and over time and can be decomposed following

$$(7) \qquad e_{kjit} = a_{kj} + b_{ji} + c_{jt},$$

where a_{kj} is the crop effect, b_{ji} is the farm effect and c_{jt} is the time (technological) effect. Introducing (7) into (6) and aggregating over crops yields the estimable form

$$(8) \qquad X_{jit} = \sum_{k=1}^{K} (a_{kj} + b_{ji} + c_{jt}]\frac{R_{kit}}{W_{jt}} + \zeta_{jit}, j = 1, \ldots, J; \quad i = 1, \ldots, I; \quad t = 1, \ldots, T;$$

where ζ_{jit} is a random deviation associated with farmer i, input j, and time t. For empirical purposes, ζ_{jit} is assumed normally and independently distributed.[6]

The estimated parameters of equation (8) can be used to translate revenue data into profit maximization estimates of variable input allocations among crops following

[5] The work of Hornbaker, Dixon, and Sonka suggests a heteroscedastic specification for the disturbance in general, but it does not appear necessary in the sample of this paper.

[6] A recent paper by Hornbaker, Dixon, and Sonka uses an alternative cost function approach which in the notation of this paper follows:

$$W_{jt} X_{jit} = \sum_{k=1}^{K} c_{kjit} L_{kit},$$

where c_{kjit} are ad hoc functions of acreages, yield, and hired labor. Although this function is represented as following from Just, Zilberman, and Hochman, it is clear from (8) that this equation cannot follow under profit maximization unless c_{kjit} involves the price of crop k. One must thus conclude that their empirical work is in the spirit of the behavioral model in (3) rather than a profit maximization model such as Just, Zilberman, and Hochman's. Indeed, if $c_{kjit} = \alpha_{kj} + \beta_{ji} + \gamma_{jt}$ and input prices are constant within the sample (as they argue for their partitioned samples), then the two models are identical. An assumption of cost minimization alone is not sufficient for specification of multi-output cost equations because both outputs and input-output ratios respond to output prices in general.

$$(9)\qquad \hat{X}^{p}_{kjit} = (\hat{a}_{kj} + \hat{b}_{jt} + \hat{c}_{ji})\frac{R_{kit}}{W_{jt}},$$

where $\hat{a}_{kj}$, $\hat{b}_{ji}$, and $\hat{c}_{jt}$ are the estimates of parameters in (8) and the superscript p denotes the profit maximization model. Comparison of equations (4) through (9) reveals the difference between the behavioral and profit maximization models. Both models require data on total variable input use. While the behavioral model requires data on land allocation among crops, the profit maximization model requires data on revenue distribution among crops and variable input prices (or simply total variable input expenditures if both sides of the estimating equation are multiplied by input price). Crop, time, and farmer effects are multiplied by the land allocation in the behavioral model, while they are multiplied by the ratio of revenue to input price in the profit maximization model.

An Application to the Estimation of Input Allocations

An illustrative application of the framework is provided by an empirical analysis of farm production data from two villages, Hazeva and Ein-Yahav, in the Arava region of Israel. This desert region is similar in production practices and technology to the Coachella Valley of California. It specializes in production of off-season vegetables. The villages consist of 85 to 101 farm units per village, respectively. Interviews with farmers revealed that individual farmers are independent producers and decision makers, but inputs are purchased and outputs are sold through cooperatives.

While the farms are small in land area compared to most U.S. farms, agricultural practices are intensive, with revenues in the neighborhood of $80,000 per farm. Most farms use computerized accounting systems similar to those available in the United States. Farmers rely on extension agents and communication with other farmers to learn about appropriate production practices, and they adapt available information to their individual situations. This suggests a framework with similar perceptions, but individualistic adaptations. The independent nature of individual farmers is reflected by a wide variation in the share of land allocated to different crops among farms.

Through a series of nontechnical questions, it was apparent that farmers behave as if their production functions follow constant returns to scale. Consistent with these perceptions, recommended input-output ratios (norms) are developed and distributed by the farm advisers. These norms are regarded much like U.S. crop budgets; it is not clear to what extent the norms are designed to guide optimal behavior as opposed to summarizing average regional behavior. Individual farmers take the norms into consideration but deviate according to their specific personal and locational characteristics.

Data on total water use and purchased input expenditure as well as on revenues by crop were obtained from the village's accounting offices. Available data are for the years 1973–82 for Ein-Yahav and 1977–82 for Hazeva. All monetary data were converted to real terms. Land allocations were available from crop insurance records. The number of inputs that can be analyzed by this methodology is determined by the number of input categories that are tallied separately and consistently in the sample population. Unfortunately, for the sample used here data on only two inputs were available. This breakdown is the most important for farming in this region because water is the most scarce local input and is the major constraint on growth of the region; knowledge of water use patterns is needed for policy and planning purposes. All other inputs are purchased externally and are of primary interest both to farmers and those granting credit as they affect overall credit needs. Although the data only divide inputs into two categories, this application serves to illustrate the methodology which easily generalizes to many inputs.

Behavioristic Estimates

The ordinary least squares estimates of parameters of equation (4) for two inputs—water and "other" inputs (as measured by expenditures)—and five outputs—bell peppers, tomatoes, onions, melons, and eggplant—are presented in table 1. Table 1 contains the estimates of the α_{kj}'s. and γ_{jt}'s. The numerous estimates of the β_{ji}'s are not reported to save space but are reflected in graphical results discussed below. In order to prevent singularity of the explanatory variable matrix, the results are normalized on the fiftieth farm and the year 1980 in each case. That is, $\beta_{50,j} = \gamma_{j,1980} = 0$, so the α_{kj}'s measure the per dunam inputs of the fiftieth farm in 1980 (a dunam is 1,000 square meters).

The water input is measured in cubic meters per dunam. Thus, for example, the coefficient for bell peppers in Hazeva implies that the av-

R^2	.971	.955	.965	.961

Note: Water input is in cubic meters; other expenditures are in 1980 shekels. Numbers in parentheses are t-ratios.

erage water application on farm 50 in 1980 is 1,411 milimeters. This water application rate converts to acre feet per acre by dividing by 304.8. Thus, the water application rate on farm 50 in 1980 is 4.63 acre feet per acre. Similarly, the coefficient for 1977 in the Hazeva water equation implies that water use averaged 184 milimeters (.60 acre feet per acre) less than 1980. These annual variations represent a response to both prices and temperature. Other inputs are measured in 1980 shekels, so the coefficients of individual crops measure average real expenditure for farm 50 in 1980 with year coefficients measuring annual deviations from 1980. A test of the hypotheses of no difference in input use per dunam among farmers ($\beta_{ij} = 0$ for all i and j) was rejected at the 1% level.

Table 1 shows that all of the crop coefficients (α_{kj}'s) are different from zero at high significance levels. Furthermore, the crop coefficients dominate the time coefficients (γ_{jt}'s). In 1980 (the base year), the average consumption of water by most crops in Hazeva was higher than in Ein-Yahav, even though water prices were not substantially different. Upon noting that the time coefficients of Ein-Yahav are larger than Hazeva, however, it is not clear that the estimates for 1980 alone give a clear picture of input use over the entire sample period.

For this purpose, table 2 presents the average estimated input use over the last six years of the sample (see the lines labeled "behavioral"). Observations are available from both settlements for these years. The sample average water use coefficients indicate that water use per dunam by crop differs little between the two settlements except in bell peppers and eggplant, even though the difference among crops is quite large. Consistent with farmer interviews, melons use considerably less inputs than all other crops. The sharp difference in water use levels on bell peppers is consistent with observed cropping patterns. Ein-Yahav is much more specialized in bell pepper production than Hazeva. One plausible explanation is that the lower water coefficient for Ein-Yahav reflects a comparative ad-

Note: Water input is in cubic meters; other expenditures are in 1980 shekels.

vantage in bell pepper production.

An explanation suggested by interviews with farm advisers is that Ein-Yahav specializes in bell peppers because it is less labor intensive and Ein-Yahav strongly adheres to the principle of self-reliant labor use for ideological reasons. If labor and water are complementary inputs, which seems plausible, then water use is lower when labor is limited. Unfortunately, no labor data are available to examine this possibility because most nonfamily labor is by unpaid volunteers who exchange services for room and board. The complementarity of water and harvest labor is particularly apparent in table 2 because water use is virtually the same in both settlements for onions and melons (crops harvested mechanically), while water use is lower in Ein-Yahav for bell peppers and eggplant (crops harvested manually).

Similar conclusions apply to other inputs as well. Small differences among crops exist between the settlements except for eggplant, while melons require only about half the other expenditures of other crops. Melons are generally a low-effort, low-revenue residual crop, while the other crops except for eggplant are considered as high-value cash crops. Eggplant is regarded as a high-value crop by Hazeva and a marginal crop by Ein-Yahav. The intensity of input uses differs accordingly.

Some of the time coefficients for water use require special explanation. In Ein-Yahav, water use in the first year was considerably more than in the rest of the period because the settlement was new and soils required initial leaching (around 300 cubic meters per dunam). The differences between other years mostly reflect climatic conditions. The lower levels of use after 1978 may reflect increasing use of drip irrigation technology and computer automation of irrigation applications.[7]

The time coefficients of other expenditures increase over time during the 1970s (Ein-Yahav). The coefficients of the late 1970s are substantially higher than the early 1970s. This rise likely reflects substantial movement toward the use of plastics and computers with drip irrigation systems. The decline after 1979 may be due to learning and a misreporting of fixed expenditures as variable expenses. Finally, according to local farm advisers, 1978 and 1979 required more expenditures on other inputs because of high energy prices and problems requiring exceptionally high pesticide use. The high level of expenditures in 1982 may be due to inefficiency connected with an exploding inflation process (to over 300% per year) which required a financial "learning by doing" adjustment.

Profit Maximization Estimates

Table 3 presents the estimates of equation (8) for water and expenditures on other inputs for the five crops and two settlements. These estimates correspond to the behavioral estimates in table 1. Again, only the crop and input coefficients are presented, while the more numerous farmer coefficients are not reported in tabular form. The farmer effects in most cases are not significantly different from zero individually,

[7] Note that as technologies were changed, farmers continued to use only one technology on each crop.

while the time and crop effects are mostly significant.

The coefficients in table 3 are interpreted according to the specification of equation (8). The coefficient for each crop in the water equation measures average water elasticity implied by profit maximization for farm 50 in the year 1980. The time dummy coefficients measure deviations in this elasticity for other years from 1980. The coefficients of the equations for other inputs measure similar concepts for expenditures per dunam.

Statistical Comparison of Alternative Models

An obvious criterion to compare the models estimated in tables 1 and 3 is the R^2 statistic. Both models obtain high and nearly similar R^2 statistics. However, for both inputs and both settlements, the behavioral model fits the data better. In the case of Ein-Yahav, the behavioral model results in about half as much unexplained variation as the profit maximization model (as reflected by $1 - R^2$). While these differences in unexplained variation are small, the superior performance of the behavioral model in four out of four cases has a significance level of .06 according to the simple signs test (on the difference in R^2 statistics between models), implying rejection of the hypothesis of equal performance by the two models. (See Siegel for details on the signs test.)

To compare more formally the profit maximization and behavioral models, a nonnested hypothesis test (Davidson and MacKinnon) was performed by including the predicted values from each model as an additional explanatory variable in the other model (see table 4). While the test is statistically inconclusive except at very high significance levels, the behavioral predictors contribute substantially more to the profit maximization model than vice versa (observe the estimated coefficients in table 4). Also, the *t*-

Table 4. Statistics for Nonnested Hypothesis Tests of Behavioral and Profit Maximization Models

	Coefficient of Behavioral Predictions in Profit Max Model	Coefficient of Profit Max Predictions in Behavioral Model
Hazeva water	0.77	0.34
	(14.23)	(5.75)
Ein-Yahav water	0.85	0.22
	(24.30)	(5.69)
Hazeva other	0.76	0.34
	(10.12)	(4.28)
Ein-Yahav other	0.87	0.18
	(22.39)	(4.17)

Note: Numbers in parentheses are t-ratios.

statistics for the behavioral predictors in the profit maximization model are considerably more significant than are the profit maximization predictors in the behavioral model in every case. Thus, the behavioral model appears superior to the profit mazimization model.

Plausibility

In order to evaluate the quality of the estimators of the variable input parameters more carefully, a standard of comparison is useful. Water use recommendations by farm advisers in the region is one plausible basis for comparison. These recommendations are reported in the line labeled "Norms" in table 2. The norms represent a range of water application rates that the advisers consider to reflect sound agricultural practices in the region. The norms are based on adviser observations of actual farmers' behavior. Thus, they are likely to include the actual regional averages; regional averages substantially outside the range of values suggested by the norms are unreasonable.

To compare the profit maximization model to the behavioral model on the basis of norms, the predicted allocations implied by table 3 are averaged over time (1977 to 1982) and farmers, and reported in the lines labeled "Profit Max" of table 2.[8] The profit maximization estimates of input use vary somewhat more among crops than the behavioral estimates. Also, some of the predictions seem unreasonable compared to the regional norms. For example, the profit maximization estimate severely overshoots the tomato water norms for Hazeva and undershoots for Ein-Yahav, while the behavioral estimate is within the recommended interval in each case. For Hazeva, all of the estimated water requirements indicated by the profit maximization model, except eggplant, are outside the regional production norms. For Ein-Yahav, three of the five estimated water requirements are substantially outside regional norms, with the eggplant estimate about 48% below the minimum bound.

By comparison, only two of the behavioral estimates are outside the production norms in Hazeva and only one estimate is outside in Ein-Yahav. The Ein-Yahav case is onions, and even then the estimate is only 5% above the upper norm. Ein-Yahav may conform more closely to the norms because it is an older and larger settlement; because of more experience, farm advisers give greater weight to Ein-Yahav than Hazeva in formulating norms. Furthermore, the other cases where behavioral estimates exceed the norms conform reasonably to farm adviser perceptions of producer behavior. For example, farm advisers indicated that Hazeva farmers tend to overirrigate peppers. Also, the average use of water on eggplant on the two settlements combined is within the norms which are intended to apply as regional averages.

Turning to the other expenses, the major differences between the two sets of estimates is that the profit maximization estimates are higher for Hazeva tomatoes and lower for Ein-Yahav tomatoes and eggplant. Again, the behavioral model corresponds closely with the views of farm advisers, who indicated that tomatoes, onions, and eggplant require about the same level of expenditures while melons requires considerably less. Thus, the estimated allocations based on profit maximization appear inferior to those based on the simple behavioral model both from the

[8] Table 2 reports weighted averages obtained by summing estimated water use over time and farms and dividing by total land allocated to the crop.

standpoints of statistical fit and practical experience.

Distributional Analysis

Because one objective of this paper is to determine variable input allocations among crops, a more complete examination of the predicted allocations is appropriate. The predicted allocations of water and other inputs were derived by each of the models for each farmer, year, and crop. These predictions were then used to form empirical probability density functions of water and other use per dunam. While space constraints prohibit presenting graphical results for all crops, the distribution of predicted water allocations for each model is depicted in figure 1 for bell peppers (the most important crop in each settlement).

Figure 1 illustrates an additional dimension in the comparison of models. The distribution of predictions for the behavioral model (reported in solid lines) is concentrated in a reasonable range as judged by the production norms with no outliers, whereas the profit maximization model has a much wider spread and yields some unreasonable predictions. All of the behavioral model predictions in Hazeva fall within 900 to 2,100 cubic meters per dunam, with virtually all predictions between 1,200 and 1,800; in Ein-Yahav, all predictions fall in the range of 700 to 1,600, with most between 900 and 1,400. By comparison, the profit maximization model pre-

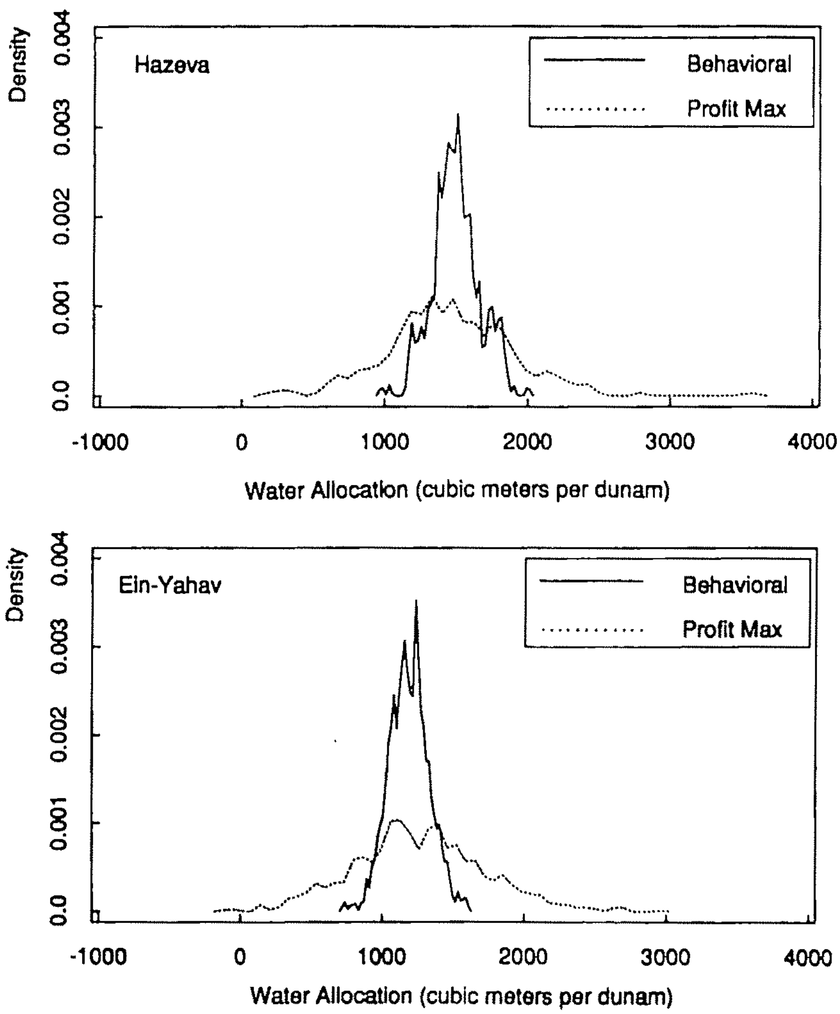

Figure 1. The water allocation distribution for peppers

dicts negative allocations in Ein-Yahav and an unreasonably high level of 3,000 cubic meters per dunam (approximately 10 acre feet per acre) in both settlements.

The results were similar for each of the other crops. However, some of the predictions by the profit maximization model were even more troubling. For tomatoes, the behavioral model predictions were concentrated in in a range of about 700 cubic meters per dunam; however, the profit maximization model predicted substantial activity over a range of 2,000–3,000 cubic meters per dunam. For onions and melons, the profit maximization model indicated substantial concentrations near zero water use, which is unreasonable in the desert conditions of this study. The profit maximization results for eggplant in Ein-Yahav indicated a zero mode of the water use distribution; these results are even more absurd. In contrast, the heavy concentrations predicted by the behavioral model corresponded well to regional norms. The predicted allocations for Ein-Yahav concentrate heavily within the norms reported in table 2. This is plausible because the farm advisers rely more heavily on the older, more established settlement in formulating their norms.

Another purpose of this study was to develop cost accounting information for individual farmers to use in decision making. Because of frequent nonsensical results produced from profit-maximization-based models, farmers considered their predicted allocations useless. On the other hand, the predicted allocations from the behavioral model have been adopted for practical use.

Conclusions

Farm management economists have the problem of allocating variable inputs among crops in formulating enterprise budgets from typical accounting data. The USDA faces similar problems in its legislatively mandated cost of production studies. Using data only on aggregate variable input use and land allocation, this paper suggests a methodology that holds potential for improvement of regional crop budget information. For the sample data used in this study, regressing total input use on land allocations allowing for crop, time, and farmer effects gives an adequate basis for allocating variable input use among crops. By comparison, procedures based on profit maximization are found to yield inferior results.

This paper does not argue that farmers do not pursue profits. Variations in the time coefficients in the behavioral model are likely in response to changes in prices and economic conditions. Similarly, differences in individual coefficients among farmers may at least partially reflect adjustments to increase profitability. Yet, the simple profit maximization model by itself does not seem to provide the best explanation of farmers' observed behavior. Lack of information, limited computational abilities, and the high cost of information gathering and processing (in short, all of the factors that come into play with bounded rationality) may cause the behavior of farmers to be better explained by a simple behavioral model than by a simple profit maximization relationship. If so, then much of the empirical analysis and associated interpretation based on simple profit maximization models may be misleading. This conclusion underscores the challenge to obtain estimable relationships that generalize profit maximization to include informational and data processing limitations and costs.

Two Practical Procedures for Estimating Multivariate Nonnormal Probability Density Functions

C. Robert Taylor

This article presents two procedures for empirically estimating nonnormal joint probability density functions (pdf's) that are operational with small samples. One procedure empirically estimates marginal distributions. Estimated marginal distributions are then used to transform variates to univariate normality; the transformed variates are assumed to have a multivariate normal distribution. The second approach exploits the identity that a joint distribution is the product of a conditional pdf and a marginal pdf. Conditional and marginal pdfs are individually estimated with this approach. Statistical tests for multivariate normality are also reviewed.

Key words: density estimation, multivariate normality tests, stochastic simulation.

Empirical determination of the probability density function of economic variables is critical in many stochastic analyses. Examples include the evaluation of crop insurance programs, stochastic simulation of firms or the economy, and normative studies based on safety-first or stochastic dominance criteria. For analytical convenience, the normal distribution is often used, although substantive empirical evidence suggests that returns, yields, and many other random variables are not normally distributed (Anderson, Antle, Antle and Goodger, Buccola, Day). Furthermore, sets of random variables, such as crop yields or returns associated with alternative production activities, may be highly correlated.

To overcome the potential biases of stochastic decision analyses based on mean-variance analysis (i.e., normality), Antle suggested a procedure for estimating third and higher moments of univariate or multivariate probability distributions, while Collender and Chalfant suggested an empirical moment-generating function approach. Although the moments uniquely define the probability distribution, it may be infeasible to specify the analytical form of this distribution. For studies based on the moments per se (e.g., a Taylor's series approximation of an objective function), Antle's procedure and the Collender and Chalfant approach are useful. However, a moment-based approach may not be operational for studies that require the probability distribution per se, such as optimization with safety-first or certain stochastic dominance criteria, or stochastic simulations with firm-level or aggregate models.

Several sophisticated nonparametric density estimation procedures have been proposed in the statistical literature, such as kernel estimates (Parzen, Rosenblatt), nearest-neighbor estimates (Loftsgaarden and Quesenberry), and projection pursuit (Friedman, Stuetzle, and Schroeder). These procedures produce an explicit expression of the pdf. However, application of these procedures is severely restricted because convergence requires quite large samples (Duda and Hart, pp. 92–95, 103; Friedman, Stuetzle, and Schroeder, p. 605) which are rarely available in agricultural economics studies. Moreover, pdfs obtained by nonparametric methods are difficult to use in stochastic simulation because the cumulative distribution, which is required for deviate generation, can be obtained only by analytical or numerical integration of the exceedingly complex mathematical expression for the pdf.

This article presents two operational approaches to empirically fit nonnormal joint probability density functions (pdfs) with data from small samples. One method is closely akin to a translation system proposed by Johnson; this approach empirically fits marginal distributions.

C. Robert Taylor is ALFA Professor of Agricultural and Public Policy at Auburn University.

Constructive comments by Oscar Burt, Earl Swanson, Robert Collender, and Paul Fackler are gratefully acknowledged.

The fitted marginal distributions are then used to transform observations to univariate normality. The set of transformed variates are assumed to have a multivariate normal distribution. A second approach exploits the identity that a joint pdf is the product of a conditional pdf and a marginal pdf. This identity is usually referenced in the case of only two random variables. It can be extended to any number of variates. Conditional and marginal pdfs are individually fitted with this approach.

Both approaches are operational with the small samples often encountered in agricultural economics. Furthermore, the approaches are especially useful in stochastic simulation models because random deviates for the nonnormally distributed random variables can be indirectly obtained from available univariate deviate generators.

The two procedures for fitting multivariate pdfs are presented in this article, and their use in stochastic simulation is discussed. Then, statistical tests for multivariate normality are presented. Empirical estimates of the joint pdf for corn, soybeans, and wheat yields are presented to illustrate the statistical tests and density estimation methods.

The Normal Transformation Approach

One approach to fitting joint pdfs is based on the idea of transforming a set of random variables, (y, x), to another set of random variables, (y', x'), which has a more convenient distribution (Mardia, p. 24). This idea was first proposed by Edgeworth in 1896. However, the particular transformation he proposed was too restrictive, and fitting the transformation by the method of moments was tedious at the time (Mardia, p. 24). A more successful version was developed by Johnson. He proposed the transformation $Z = T(Y)$, where $T(\cdot)$ was of an assumed form (lognormal, logit normal, or inverse hyperbolic sine) and where Z had a normal distribution. The set of transformed variables was assumed to have a multivariate normal distribution. Johnson's three transformations were proposed partly because of their curvature, but largely because they could be analytically manipulated and estimation of associated parameters was practical at the time.

With present computational power, it is no longer necessary to restrict the class of transformations to a small set of assumed forms or restrict the class to those that can be parameterized by a simple approach such as the method of moments. The variable transformation approach can be made more flexible by using any appropriate technique for fitting a marginal pdf; thus, marginal distributions can be fitted arbitrarily well. The fitted marginal distributions may then be used to transform (numerically or analytically) the original observations to univariate normality. The transformed observations can be used in a straightforward way to calculate the correlation matrix for the multivariate normal distribution.

Johnson's class of transformations was restricted because he needed a closed-form inverse transformation. Analytical requirements thus severely restricted the usefulness of Johnson's approach. Although most of the flexible methods for fitting a pdf do not result in a closed-form inverse expression, they are useful because the inverse transformation can be numerically obtained as follows.

Let $FN(y')$ be the cumulative distribution function (cdf) for a standard normal variable, y', and let $F(y)$ be the empirically estimated cdf. For the ith observation on y, the associated transformed observation is given by the root of the equation,

$$F(y_i) - FN(y_i') = 0. \tag{1}$$

The relationship between y_i and y_i' is illustrated in figure 1. Given the untransformed observation, y_o, the empirical marginal pdf is used to find the probability of this or a smaller value of y occurring. This probability is given by F_o in figure 1. Given this value of F, the associated value of the transformed variate, which is y_o', is obtained from the standard normal distribution.

Equation (1) can be solved using one of several numerical techniques for finding roots. Newton's technique, which is based on a linear approximation to (1), is simple and usually works well for this problem.

A closed form approximation for $FN(\cdot)$ can be used to avoid repeated numerical integration of the normal pdf to obtain the cdf used in (1) (see e.g., Taylor 1981, p. 9). Furthermore, a density estimation technique that gives a closed form expression for the distribution function can be used to avoid numerical integration of the empirically estimated pdf. An example of such a method was proposed by Taylor (1984). Other univariate density estimation methods that could be used for fitting marginal pdfs are referenced in Taylor (1984).

Solving (1) for each observation produces a standard normal variate set. This process can be

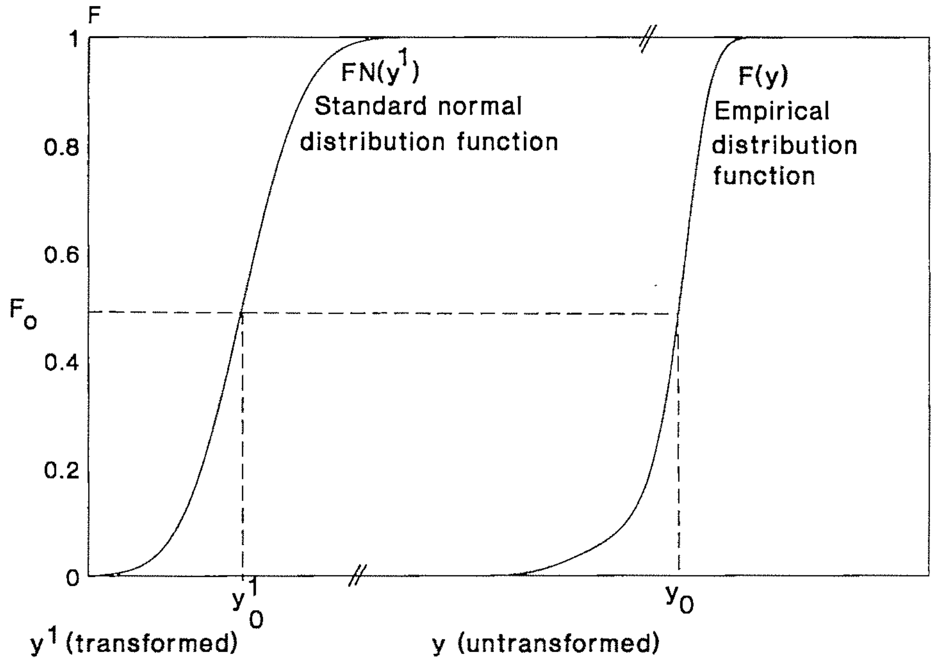

Figure 1. Illustration of the transformation of observations

repeated for each variable. Covariances computed from this data set fully parameterize the multivariate normal distribution which, along with the marginal pdfs for the untransformed data, are assumed to fully characterize the joint pdf of the original variates.

As noted by Mardia, a potential shortcoming of the variable transformation approach is that only one parameter (the correlation coefficient or covariance) describes the interrelationship between each pair of transformed random variables. However, the transformation approach should not be summarily dismissed unless multivariate normality tests of the transformed data indicate a departure from normality. Of course, with small samples, we may not have the luxury of using more than one parameter to characterize variable interrelationships. Furthermore, it is important to note that the method will handle variable interrelationships at least as well as methods in common use.

Use of the Normal Transformation Procedure in Simulation

Use of such a joint pdf in a stochastic simulation model proceeds in reverse from the steps used to obtain the nonnormal pdf. Deviates from a multivariate standard normal deviate generator give values such as y_o' in figure 1 for each variable. The random deviate for the untransformed variate is given by solving (1) for y_o given y_o'. Proceeding in this way for all variates gives the set of deviates for the untransformed (nonnormally) distributed variates obtained from the set of deviates generated by the multivariate normal generator. The availability of multivariate normal deviate generators thus makes the above procedure attractive for simulation.

The Conditional Distribution Approach

Another approach (Duda and Hart, p. 113) to approximating joint pdfs is based on the identity

$$(2)\quad f(y_1, y_2, \ldots, y_d) \equiv f(y_1)f(y_2|y_1)f(y_3|y_2, y_1) \ldots f(y_d|y_{d-1}, \ldots, y_1),$$

where d is the number of jointly distributed random variables. Although the conditional relationships on the right-hand side of (2) could be specified in $d!$ ways, the specification used makes no theoretical difference as long as a sufficiently flexible method is used to empirically fit the distribution.

With the identity approach the number of parameters required to fit the distribution conditioned on the $(d - 1)$ variables may be large relative to the number of observations. However, with many empirical problems, one variable may be dependent on only a few of the other variables, thereby making the approach operational. The method proposed by Taylor (1984) can be used to fit the conditional as well as marginal pdfs in (2).

Use of the Conditional Distribution Procedure in Stochastic Simulation

Generation of stochastic deviates from a joint pdf obtained by exploiting identity (2) must proceed sequentially from obtaining a deviate for the random variable represented by the marginal pdf to a deviate for the random variable represented by the pdf conditioned on all other random variables in (2). Generation of a set of d deviates based on (2) requires d deviates from independent, uniformly distributed random variables. Given such a set of uniformly distributed deviates, generation of deviates for the random variables, y_i, can proceed as follows. A deviate for y_1 can be generated using the cumulative distribution, $F(y_1)$, and a deviate from a uniform distribution. Given this deviate, another uniform deviate can be used with the conditional cumulative distribution, $F(y_2|y_1)$ to obtain a deviate for y_2. This process sequentially continues, culminating with a deviate, y_d, obtained from $F(y_d|y_{d-1}, \ldots, y_1)$ given the deviates $y_1, y_2, \ldots, y_{d-1}$.

Tests for Multivariate Normality

Before empirically fitting distributions to data, it is informative to test whether the data could have been generated by a common theoretical distribution, especially the normal distribution. Statistics commonly used for testing for univariate normality are Pearson's skewness parameter, $b_1^{0.5} = m_3/m_2^{1.5}$, Pearson's kurtosis parameter, $b_2 = m_4/m_2^2$ (Snedecor and Cochran), Geary's kurtosis parameter, $a = mad/m_2$, and the Shapiro-Wilk parameter, $W = c^2/m_2$, where m_i is the ith moment around the mean, mad is the mean absolute deviation, and c is the regression slope of the ordered sample observations on the expected values of the normal order statistics. Buccola discusses use of these statistics in testing for univariate normality of yield, price, revenue and cost series.

Malkovich and Afifi have generalized the Shapiro-Wilk normality test and Pearson's tests for skewness and kurtosis to test the hypothesis of multivariate normality. Machado will be paraphrased to briefly describe the test developed by Malkovich and Afifi. Let the data be $Y_1, Y_2, \ldots, Y_n$, where $Y_i = (y_{i1}, \ldots, y_{ip})'$ is a $p \times 1$ vector of observations. For arbitrary r in the space of all p vectors of unit length, let $\{y_i(r)\} = \{r'Y_i\}$ be the univariate sample obtained by projecting the multivariate sample along r. Directional measures of skewness, kurtosis, and Shapiro-Wilk departure from normality can be obtained, respectively, by computing $b_1(r)$, $b_2(r)$, and $W(r)$ for the univariate projection, $y_i(r)$, of the multivariate sample. Applying Roy's union-intersection principle of test construction to the univariate tests (Malkovich and Afifi) results in the multivariate skewness statistic $b_{1,p} = \max\{b_1(r)\}$, two multivariate kurtosis statistics, $b_{2,p,\max} = \max\{b_2(r)\}$ and $b_{2,p,\min} = \min\{b_2(r)\}$, and the Shapiro-Wilk statistic, $W_{\min} = \min\{W(r)\}$, where each optimization is taken over the unit vector, r.

Optimization required to compute the multivariate test statistics is not a trivial numerical problem. In fact, numerical calculations required to compute accurately the test statistics for several random variables may exceed the numerical calculations required for a simulation model or for an economic optimization model using the joint probability density function. When more than four or five random variables are involved, the task of computing multivariate test statistics or relying on univariate test statistics along with visual inspection of scatter plots is an onerous one. Theoretical considerations would dictate that all statistics are computed, while practical (time, resources, and so forth) considerations in empirical analyses might dictate the latter choice.

With two or three variates, a fine grid search is practical for computing multivariate test statistics. However, with more variates, more systematic numerical search techniques could be employed.

Machado has given a method for calculating approximate percentage points of the distribution of the above multivariate normality test statistics. Simulation studies in Machado show that the approximations are good for sample sizes of 25 and above for dimensions of 2, 3, and 4; however, accuracy of the approximation for p greater than 4 has not been examined.

Monte Carlo studies show that with small samples the power of the tests for $p = 2$ is adequate, but not high, against some alternatives (Malkovich and Afifi). Like univariate tests (Buccola), however, there is great risk in not detecting nonnormality with the small sample sizes, say 10 to 50, often encountered in empirical research.

Empirical Application

Univariate and multivariate test statistics for linearly detrended corn, soybean, and wheat yields in Macoupin County, Illinois, for the 1945–87 period are given in table 1. Test statistics distinctly show univariate and multivariate skewness, kurtosis, and nonnormality in the data set. Test statistics for univariate and multivariate normality computed from logarithmically transformed yield data are also highly significant.

The joint pdf of linearly detrended per acre yields of corn, soybeans, and wheat was fitted to illustrate the two procedures. A polynomial approximation of the cumulative distribution (cdf) constrained to the zero-one range by a hyperbolic tangent (Taylor 1984) was used to fit all marginal and conditional pdfs required with the two approaches. The form of the conditional cdf is

$$(3)\quad F(y_j|y_{j-1}, \ldots, y_1) = 0.5 + 0.5*\tanh(P(y_j, y_{j-1}, \ldots, y_1)),$$

and the associated conditional pdf is

$$(4)\quad f(y_j|y_{j-1}, \ldots, y_1) = 0.5*P^j(y_j, y_{j-1}, \ldots, y_1) *\text{sech}^2(P(y_j, y_{j-1}, \ldots, y_1)),$$

where $P(\cdot)$ is a polynomial function, P^j is the partial derivative of $P(\cdot)$ with respect to y_j, $\tanh(\cdot)$ is the hyperbolic tangent, and $\text{sech}(\cdot)$ is the hyperbolic secant. Parameters characterizing $P(\cdot)$ are estimated by maximum likelihood applied directly to the log-likelihood function based on (4).

The polynomial approximation was restricted to a cubic function for the empirical application because the cubic provides a reasonably accurate approximation of most unimodal pdfs. A self-contained computer program for maximum likelihood estimation of the pdf for the cubic approximation is available from the author. Theoretical and practical limitations of the procedure are discussed in Taylor (1984).

The Normal Transformation

Maximum likelihood estimates of the marginal pdfs for corn, soybeans, and wheat are given in table 2. The Schwarz model selection criterion was used to determine which cubic terms to include in the final model. Experience in applying the hyperbolic tangent approach to many data sets shows use of the Schwarz criterion to be generally consistent with addition or deletion of individual polynomial terms based on asymptotic t-values.

The procedure outlined in figure 1 and equation (1) was used to transform the raw detrended crop yield observations to univariate standard normality based on the fitted marginal pdfs in table 2. Univariate test statistics for normality shown in table 3 do not reject normality of the transformed data, which suggests that the marginal distributions in table 2 fit the data reasonably well.

Table 1. Univariate and Multivariate Tests of Distributional Shape Based on Detrended Macoupin County, Illinois Crop Yield Data, 1945–87

Random Variable	Skewness b_1	Kurtosis b_2	Kurtosis a	Normality W
UNIVARIATE TESTS				
Corn	−1.40***[a]	6.05***	0.73**	0.90***
Soybeans	−1.46***	5.81***	0.77	0.88***
Wheat	1.80***	9.33***	0.69***	0.87***
MULTIVARIATE TESTS				
All	−1.84***	9.43 (max)*** 2.29 (min)		0.87 (min)***

[a] One, two, or three asterisks denote statistical significance at the 10%, 5%, or 1% level, respectively. Critical values for b_1 and b_2 were computed from approximation formulas given in Machado; critical values of a were obtained from Geary; and critical values of W were obtained from Shapiro and Wilk.

Table 2. Hyperbolic Tangent Approximation of Marginal Probability Functions for Corn, Soybeans, and Wheat Yield

Crop	Maximum Likelihood Estimate of[a] β_1	β_2	β_3	β_4
Corn	−0.1308	2.9497	0.8182	
	(0.97)	(7.83)	(2.47)	
Soybeans	−0.2458	2.3501	1.7590	0.7614
	(1.71)	(7.33)	(2.95)	(1.82)
Wheat	0.1042	1.3140	−0.137299	
	(0.79)	(7.76)	(2.61)	

Note: Distributions were fitted to deviations from an OLS linear trend model. Deviations from the trend were scaled (multiplied) by 0.02, 0.10, and 0.10 for corn, soybeans, and wheat, respectively, to avoid numerical difficulties in obtaining maximum likelihood estimates of the parameters of the pdf.

[a] The form of the distribution function, $F(y)$, is

$$F(Y) = 0.5 + 0.5 * \text{TANH}\,[\beta_1 + \beta_2 Y + \beta_3 Y^2 + \beta_4 Y^3].$$

The associated probability density function $F(Y)$ is

$$f(Y) = 0.5 * (\beta_2 + 2\beta_3 Y + 3\beta_4 Y^2) * \text{SECH}^2\,[\beta_1 + \beta_2 Y + \beta_3 Y^2 + \beta_4 Y^3].$$

Asymptotic t-values are given in parentheses.

Transformed data were used to estimate the correlation matrix given in table 4. Since the standard normal cdf was used in equation (1), the transformed variates have mean zero and variance one. The transformed variable correlation matrix in table 4 along with the marginal pdfs given in table 1 completely characterize the multivariate nonnormal crop yield probability density function obtained using the transformation approach.

Multivariate test statistics for the transformed data set, which are shown in table 3, show marginal significance at the 5% level for skewness (max b_1), and significance at the 10% level for kurtosis (min b_2). The nonnormality (min w) test was not significant. A comparison of the multivariate test statistics shown in table 1 (untrans formed data) with multivariate test statistics i table 3 (transformed data) weakly suggests tha a single parameter (the correlation coefficien may not be sufficient to describe the interrela tionship between the transformed variates in thi particular case. However, comparison of statis tics in tables 1 and 3 clearly reveals that for th given sample of yield data, the transformatio procedure results in a joint pdf that is better tha the multivariate normal pdf; thus, use of th normal transformation procedure results in les bias in this empirical example than use of th multivariate normal distribution for the raw data

The Conditional Distribution Approach

Consider now an application of the identity ap proach to fitting a joint distribution for cro yields. The hyperbolic tangent approximation t pdfs for each yield variable conditional on th other two yield variables was considered. Esti mates with asymptotically significant coeffi cients are shown in table 5. Only corn and soy bean yield distributions were significantly relatec which is consistent with the low correlation (table 4) of wheat and soybean yields, and whea and corn yields.

Comparison of Empirical Fits

In comparing alternative empirical fits of join pdfs, statistical tests should be conducted to de termine which fitted pdfs are significantly bette than others. With the present state of develop ment of nonnested hypothesis tests, however, test with well-understood small sample proper ties is not available (Judge et al., p. 885). Thus the alternatives can only be ranked using value of the likelihood function or using an informa

Wheat	0.1756	0.1876	1.0000
Transformed observations:			
Corn	1.0000		
Soybeans	0.8017	1.0000	
Wheat	0.2063	0.2099	1.0000

Table 5. Hyperbolic Tangent Approximation of Conditional Probability Functions for Corn and Soybean Yield

	Maximum Likelihood Estimate of[a]			
pdf	β_1	β_2	β_3	β_5
$f(Y_{co}\|Y_{sb})$	−0.1412	5.1959	0.8579	−3.3314
	(0.97)	(7.80)	(1.66)	(6.04)
$f(Y_{sb}\|Y_{co})$	0.0236	4.0066		−4.3335
	(0.18)	(7.90)		(6.26)

[a] The form of the pdf is

$$f(Y_i|Y_j) = 0.5 * (\beta_2 + 2\beta_3 Y_i + 3\beta_4 Y_i^2) * \text{sech}^2 (\beta_1 + \beta_2 Y_i + \beta_3 Y_i^2 + \beta_4 Y_i^3 + \beta_5 Y_j),$$

with $i \neq j$, and with *co* designating corn and *sb* designating soybeans.

tion criterion, such as the Schwarz criterion. Joint probability density functions for the crop yield variables fitted with various approaches are compared in table 6. Relative ranking of the models based on the value of the likelihood function from worst to best is univariate (independent normality), multivariate normality, the conditional distribution approach with soybean yield conditioned on corn yield, the transformation approach, and the conditional distribution approach with corn yield condition on soybean yield. Relative ranking of the models using the Schwarz criterion was the same, except that both conditional distribution fits were better than the transformation approach. The Schwarz criterion penalized the larger number of parameters used in the transformation approach compared to the conditional approach.

Concluding Comments

This article presents two procedures for empirically fitting multivariate nonnormal probability density functions. One procedure transforms variates to multivariate normality based on fitted marginal pdf's, while the second procedure exploits a fundamental identity in probability theory that a joint distribution is the product of a marginal and a conditional probability density function. Both procedures are small sample alternatives to assuming a particular theoretical distribution for empirical analyses. Either procedure will work at least as well as any methods commonly used.

Implementation of the procedures results in a closed form expression of the distribution function and the probability density function. Each procedure can be adapted for generation of deviates for use in stochastic simulation.

[Received March 1987; final revision received March 1989.]

Table 6. Comparison of Alternative Estimates of the Joint pdf of Corn, Soybeans, and Wheat Yields

Model	ln (Likelihood) for Sample Data	Number of Parameters	Schwarz Model Selection Criterion
Independent normal	−89.39	6	−100.67
Multivariate normal	−60.99	9	−77.92
Multivariate normality using transformation approach[a]	−48.93	13	−73.39
Conditional identity:			
$f(Y_{co}\|Y_{sb})f(Y_{sb})f(Y_{wh})$	−47.38	10	−66.19
$f(Y_{sb}\|Y_{co})f(Y_{co})f(Y_{wh})$	−52.05	9	−68.98

[a] Applying standard theorems for obtaining the multivariate distribution of a set of functions of random variables, it can be shown that the likelihood function for the transformation approach is

$$l = \frac{f(Y_{co})}{fn(Y_{co})} \frac{f(Y_{sb})}{fn(Y_{sb})} \frac{f(Y_{wh})}{fn(Y_{wh})} \cdot g(Y'_{co}, Y'_{sb}, Y'_{wh}),$$

where l is the likelihood function, $g(\cdot)$ is the multivariate normal pdf, $f(\cdot)$ are the appropriate fitted marginal pdfs, $fn(\cdot)$ is the univariate normal pdf, Y_i are the untransformed variables, and Y'_i are the transformed variates.

Impact of the WIC Program on Food Expenditures

Gustavo J. Arcia, Luis A. Crouch, and Richard A. Kulka

Participation in the WIC program tends to shift grocery expenditures in favor of more nutritious food. Dairy data show that WIC women consumed more nutrient-dense foods than non-WIC women. WIC women and their families spent significantly less on meals away from home than control families, suggesting a more efficient use of the food budget. WIC's impact on unintended recipients is negligible, while its impact on foods for WIC children is positive and highly significant. Recall data on monthly food expenditures indicate that total food expenditures and grocery expenditures did not increase as a result of program participation.

Key words: food diary, food expenditures, WIC, WIC children, WIC foods.

The Special Supplemental Food Program for Women, Infants, and Children (WIC) is a federally sponsored program designed to provide supplemental food and nutrition education to low-income, nutritionally at-risk participants. The program serves over 3.4 million persons monthly at an annual cost of over $1.5 billion (fiscal year 1987 program data). Program participation is limited to pregnant women, post-partum women (up to six months after delivery), breast-feeding women (up to twelve months after delivery), infants (up to one year of age), and children (up to five years of age) from low-income families who are determined by a competent health professional to be nutritionally at risk. In addition, applicants must have a gross family income not exceeding 185% of the Office of Management and Budget nonfarm income poverty guidelines. Participation in other income assistance programs such as Food Stamp or School Lunch Programs does not affect eligibility.

WIC foods provide nutrients that are likely to be lacking in the diet of participants, particularly high-quality protein, iron, calcium, vitamin A, and vitamin C. The food prescription, known as a food package, contains food such as infant formula, milk or milk products, iron-fortified cereal, juice, eggs, and dried beans or peanut butter. It may be tailored to a participant's needs within federal guidelines, and it may vary in value between $28 and $32 per month on average.

This study analyzes the effects of program participation on expenditure and consumption patterns by the households involved. This food expenditures study originally was developed as a part of the *National WIC Evaluation* commissioned by the Food and Nutrition Service of the U.S. Department of Agriculture (USDA). Data for the evaluation were collected in 1983, and a comprehensive final report was published in 1986.

Data Collection Design and Methods

The *National WIC Evaluation* study combined recall and diary methods to collect information on household food expenditures, thus permitting longitudinal and cross-sectional comparisons between WIC and non-WIC households. The study sample was the nationally representative probability sample of pregnant women enrolled in WIC and the control group of non-WIC pregnant women in the *Longitudinal Study of Pregnant Women*.[1]

Data collection proceeded as follows: During the initial clinic enrollment interview, 4,219 WIC and 785 non-WIC women were asked to recall their monthly expenditures for food and bever-

Gustavo J. Arcia and Luis A. Crouch are agricultural economists at the Center for Development Policy, Research Triangle Institute, North Carolina. Richard A. Kulka is associate director for survey research at the National Opinion Research Center, Chicago, Illinois.

[1] *The Longitudinal Study of Pregnant Women* was one of the four component studies of the *National WIC Evaluation*. The others were the *Food Expenditures Study*, the *Historical Study of Pregnancy Outcomes*, and the *Study of Infants and Children*.

ages for the month immediately preceding the interview. This is referred to as "time 1" in the following discussion. The questions used were comparable to those previously developed and used in the *U.S. Quarterly Consumer Expenditure Surveys* and the *Canadian Family Food Expenditure Surveys*.[2] These questions were repeated during the second interview, late in the pregnancy ("time 2").

At the second interview, in addition to the recall assessment of food expenditures, a random sample of 1,031 WIC and 551 non-WIC women kept a detailed diary of food purchases for a one-week period following the visit, using a ledger diary similar to those employed in the U.S. and Canadian surveys. A portion of the second interview focused on the use of the diary. A monetary incentive was offered for participation in this phase of the study.

An interviewer collected the diary in a home visit in order to encourage a high level of cooperation and complete reporting. The interviewer thoroughly checked the diary for consistency and completeness, using a set of "diary check" questions for types of expenses typically forgotten, and attempted to obtain—by retrospective interview—information for days not recorded in the diary. Along with intake and expenditures data, major predictors or correlates of family food expenditures, such as family size, age-sex household composition, and household income were collected.[3]

Because diary information was recorded and collected only at the time of the second interview, a longitudinal analysis based on these data is not possible. However, the data are especially useful for comparing WIC and non-WIC households because of the greater detail they provide about the types of foods purchased. Specifically, diary data may be used to examine changes in food purchasing behavior by comparing the portion of food dollars allocated by WIC and non-WIC diary-keeping families to various types of food.

The inferences that can be drawn from this study are limited in several ways. The study emphasizes the impact on pregnant women participating in the WIC program. As in all surveys, the data are subject to measurement errors and to the families' accuracy in reporting income and food purchases. Another limitation is the lack of information on the quantity and composition of foods purchased with the WIC coupons. Because the coupons are valid for nutrient-equivalent foods, a WIC woman may, for example use her coupons to buy cheese and milk in different combinations. As a result, the data do not allow for an exact determination of the composition of the WIC package because most WIC foods would overlap with foods normally purchased for the rest of the household.

The use of recall and diary methods was intended to test the effects of WIC on food expenditures and on the consumption of foods promoted by the WIC program (WIC-type foods). However, these two methods cannot be used to cross-check dietary consumption information. The recall method is a proven, cost-effective way of gathering information about food-purchasing patterns that closely approximates actual average intake over a predefined period (Adelson; Burk and Pao). However, actual consumption could be underestimated (Madden, Goodman, and Guthrie) or actual food expenditures could be overestimated (Quackenbush and Schaeffer). Diary methods are more costly but yield more detailed data about intake by food groups. However, diary methods have biases as well. Burk and Pao found that diary estimates differed substantially from recall methods. Correlation coefficients among diary and recall methods generally are about 0.7 (Balogh, Kahn, and Medalie). In general, diary records are not representative of average long-term intake because of weekly fluctuations in the family's purchasing patterns (payday effect), recording inaccuracies, or diary-induced modifications in the types of foods consumed by the family (Burk and Pao). The correlation between diary and recall data to measure food expenditures in this study is approximately 0.49.

Despite the shortcomings outlined above, diary and recall methods remain the most cost-effective ways to collect data on food purchasing from large samples.

Estimation Procedure

The empirical model for the recall data attempts to measure the following impacts of the WIC program: (*a*) effect of WIC benefits on monthly food expenditures, (*b*) degree to which WIC benefits substituted for foods that would have been purchased anyway, and (*c*) degree to which WIC benefits were shared by nonintended ben-

[2] A complete list of the questions used is available from the authors or may be found in volume IV, appendix VII-A, of the *National WIC Evaluation*.

[3] Throughout the study the term "household" is assumed to mean a group of people who, regardless of relationship, share resources and liabilities. A household may group more than one family.

eficiaries in the family. A two-stage least squares model was developed with variables which were significant in similar nutritional assistance programs such as the Food Stamp Program and the National School Lunch Program (Adrian and Daniel; Blaylock and Smallwood; Basiotis et al.; Akin, Guilkey, and Popkin; Chen; Basiotis).

The empirical model for the diary data estimates the impact of WIC on food expenditures by food types. The food types selected for the diary analysis are a basket of foods generally found in the WIC package (WIC-type foods), meats, cereals and bakery products, vegetables, other fresh foods, and frozen foods. In addition to the food groups listed above, the diary data analysis also examines weekly expenditures on food, groceries, and meals away from home. Diary data are analyzed with ordinary least squares since they were only collected for time 2.

The impact of WIC on food expenditures using recall data is estimated by the following two-stage least squares model:

$$\begin{aligned} FE2 &= h_0 + h_1 FE_1 + h_2 W \\ &\quad + h_3 C + h_4 A + h_5(W^*C) \\ &\quad + h_6(W^*A) + lX + u, \\ FE1 &= f_1 + f_2 Y + gM + e, \end{aligned}$$

where $FE2$ is food expenditures at time 2; $FE1$, food expenditures at time 1; h_i, l, f_i, g, regression coefficients ($i = 1, \dots n$); $W = 1$ for WIC women, 0 for non-WIC women; C, number of children in the household; A, number of adults in the household including the WIC woman; X, vector of family composition and participation in other assistance programs; Y, monthly household income, as defined in the following section; M, a vector of socioeconomic characteristics including ethnicity, participation in other assistance programs, and education level of the WIC woman; and u, e are disturbances.

The empirical model for the diary data is

$$\begin{aligned} FG_i &= d_0 + d_1 Y + d_2 W + d_3 C + d_4 A \\ &\quad + d_5(W^*C) + d_6(W^*A) + lX + v, \end{aligned}$$

where FG_i is food group i ($i = 1, \dots, m$); d_j, regression coefficient for variable j ($j = 1, \dots, n$); and v, disturbance.

Coefficient h_2 in the model for recall data measures the impact of WIC participation by a pregnant woman on total household food expenditures. Coefficients h_3 and h_4 measure the effect of an extra child or adult on expenditures, and coefficients h_5 and h_6 measure the impact on food expenditures of each extra child and adult, respectively, whenever a WIC woman is in the household.

Coefficients h_3 and h_4 are expected to be large and statistically significant because household size is a main determinant of household food expenditures. Coefficients h_5 and h_6 would be statistically significant only if women's participation in the WIC program affected the impact of other adults and children on total family food expenditures over and above normal circumstances. Thus, h_5 and h_6 represent an indirect estimation of the sharing of WIC benefits by other family members. Direct sharing of WIC foods could not be estimated because intrafamily allocation of food was beyond the scope of the *National WIC Evaluation*.

The total sharing of food expenditures coming from WIC can be estimated by

$$Sharing = h_5{}^*C + h_6{}^*A,$$

where C and A represent the number of children and adults in the household, respectively. Because h_2 is the measure of the WIC program's actual impact, substitution must equal the total WIC transfer (the intended impact), *WIC*, minus sharing:

$$Substitution = WIC - (h_2 + h_5{}^*C + h_6{}^*A).$$

Since the exact value of the WIC package is not available, substitution can be approximated by replacing the value *WIC* with the range of package values reported for the WIC package (between \$28 and \$32).

The substitution and sharing of WIC benefits are entirely economic and are based on indirect evidence. Adjusting for expenditures at time 1 in the equation for $FE2$ is important. If, for example, families of WIC recipients spend more on food than other families and $FE1$ were not in the equation for $FE2$, the pre-existing difference in expenditures levels between WIC recipients and other families would be attributed improperly to the WIC program.

Definition of Variables

Food expenditures for the recall data are the sum of all reported expenditures on foods reported in the time 1 and 2 interviews. These expenditures were obtained by a trained interviewer who helped participants recall monthly expenditures on food and nonfood items bought at supermarkets, convenience stores, wholesale outlets,

restaurants, vending machines, and other food sources.

Total household income in the recall data is the sum of wage and nonwage income received by all household members. Nonwage income includes social security, unemployment insurance, food stamps, and other family assistance programs received during time 1. No information on household income at time 2 was collected. Therefore, total income does not include the value of the WIC coupons. Moreover, the exact market value of the WIC coupons is not available because they are exchanged directly for food by the WIC participant. Total income for the diary data is equal to total income at time 1 minus the value of food stamps, which are included as a separate variable in the diary analysis.

Family composition accounts for the number of infants, children between 1 and 5, 5 and 10, and 11 and 21 years of age, and the number of adults. All groups are classified by sex. Ethnicity is defined by categorical variables with a value of 1 if the respondent is white, black, and hispanic. Other ethnic groups (i.e., Asian, Pacific islander) take a reference value of 0.

The variable *Male Head Present* is used to represent civil status. This variable takes a value of 1 if a husband or male companion lives in the house and a value of 0 otherwise. Education of the WIC woman is a categorical variable with a value of 1 if the respondent completed elementary school, high school, junior high school, or post-high school. The reference value of 0 is for women who did not complete elementary school. *Lunch Program* is defined as the number of children in the household who participate in a school lunch program. *Number of Guests* is defined as the number of person/days of household guests during the month prior to the interview at times 1 and 2. The variable *Food Stamps* is categorical in the recall analysis, taking a value of 1 if anybody in the household was a food stamp recipient and 0 otherwise. In the diary analysis the variable *Foods Stamps* equals the net value of food stamps received by the household. The variables *Other WIC Women, WIC Infant,* and *WIC Child* represent the number of other women, the number of infants and the number of children in the household receiving WIC coupons.

Sample Characteristics

The study's basic sample population contains 4,219 WIC participants and 785 non-WIC participants. From this sample, a subsample of 1,031 WIC women and 551 non-WIC women was obtained for the diary data on food purchases. Characteristics of these samples are summarized in tables 1 and 2, with standard errors in parentheses.

In general, non-WIC families have higher total family incomes, and education levels and racial distribution differ as well between non-WIC and WIC families. Non-WIC families are better educated with a higher proportion of pregnant women having high school educations than in WIC families. The proportion of whites among non-WIC families is higher than among WIC families.

WIC families in the recall sample reported significantly less total food expenditures than the non-WIC families. They spent significantly less on meals away from home, and had larger food stamp allotments (see table 1). The WIC families in the diary sample reported significantly greater grocery expenditures and purchases of WIC-type foods than non-WIC families at time 2.[4] Expenditures on meals away from home were also significantly less for the WIC diary sample families (see table 2). However, no significant differences between the two family groups were found in expenditures on the other food categories.

The higher expenditure levels for WIC-type foods found among WIC families cannot be attributed to program participation alone because no diary measures exist at time 1 prior to initial enrollment in the WIC program.

Model Results

The results from the recall data (table 3) indicate that household composition is the primary determinant of total food expenditure; the coefficients associated with family composition are significant. Other important variables which increase household food expenses are the number of guest-days during the month prior to the interview and participation in the food stamp program. However, participation in the school lunch program significantly reduces food expenditures. Finally, food expenditures are unaffected by schooling, ethnicity, or the presence of a male head of household. Grocery expenditures are also determined by family composition. The regression results for grocery expenditures also show

[4] Since the exact composition of the WIC package is left at the discretion of the participant, the term "WIC-type foods" is used to describe or approximate purchases made with WIC coupons.

a positive impact of elementary education and significantly lower grocery expenditures associated with black households.

Table 3 also show the coefficients which represent substitution and sharing. The WIC coefficients for total food expenditures and grocery expenditures are not significantly different from zero, indicating no apparent increase in total food expenditures resulting solely from participation in the WIC program by women.

The recall data also show that the interaction term *WIC*adults* is negative and highly significant. Thus, the presence of each additional adult in a WIC household appears to reduce monthly total food expenditures. This significant interaction effect may be explained by the impact of WIC on meals eaten out because the difference between total food expenditures and grocery expenditures is mostly explained by expenditures on meals away from home. The last two columns in table 3 show the recall data results from expenditures on meals away from home. These results show that WIC program participation is strongly associated with a tendency to spend less on meals away from home. Families of pregnant women participating in WIC are estimated to spend $6.26 less per month on meals eaten out than the families of non-WIC women. Apparently WIC program participation contributes to a larger proportion of home-cooked meals in the family diet. Because meals away from home have an implicit cost for service that increase the cost per unit of nutrients compared to home-cooked meals, the WIC program fosters a more efficient use of the family's food budget.

Impact of WIC on Food Expenditure Patterns

The results for the recall data reflect program impact only in terms of food expenditures. This is only a partial indicator of overall program performance. It is possible, for example, to have different food consumption patterns between two time periods and still have data showing equal food expenditures. Hence, the impact of the WIC program on both food expenditures and food purchase patterns must be examined.

Table 4 presents the OLS regression results for the diary data. The columns in the table represent different food groups reported in the diary. The diary results show that participation in the WIC program has a positive impact on expenditures on WIC-type foods and a negative impact on expenditures for meals away from home. These combined results indicate that WIC has a beneficial impact on the quality of food consumed by the household and on the efficiency of the household food budget. For WIC-type foods WIC families spend $2.54 more per week than do non-WIC women and each WIC child under five years of age accounts for an additional expenditure of $2.25 per week in WIC-type foods over non-WIC children. Moreover, WIC households spend $4.10 per week less on meals away from home than non-WIC households.

Diary data also show that each additional WIC child increases grocery expenditures by $5.82 per week. The significant positive impact of WIC children on food expenditures indicates that food purchased for children are not easily substituted for foods consumed by household adults. None of the equations for the diary data shows a significant interaction between household composition and WIC participation by women.

Conclusions

The results show that the WIC program mostly influences food composition rather than food expenditures. WIC program participants buy more WIC-type foods (presumably more nutritious) than do nonparticipants, even though no significant differences in total food expenditures were found between the WIC and non-WIC groups. The food expenditures recall data, although a cost-effective source of information, provide weak evidence of program impact. However, unchanged levels of food expenditures do not imply unchanged use of WIC-type foods. Rather, the restrictive nature of the WIC program seems to influence the nutrient composition of the market basket for the WIC family. That is, the income increase generated by WIC is tied to food instruments redeemable for specific foods and to the presence of an eligible pregnant woman in the household. A WIC household receives food coupons which are more difficult to exchange for cash than coupons from other nutritional assistance programs (e.g., food stamps).

Expenditures on WIC-type foods among WIC families are significantly greater than among non-WIC families. Although there is no direct evidence that such expenditures derive from program participation, the observation that expenditures in other food groups are the same for WIC and non-WIC families provides indirect evidence. Hence, the evidence suggests a positive program impact through increased use of

nutritious WIC-type foods. Moreover, the impact of the WIC program on unintended recipients appears negligible.

Children's participation in the WIC program has significant and positive effects on both food expenditures and purchasing patterns. The evidence from both recall and diary data shows that children participating in the WIC program account for higher grocery expenditures than non-WIC children. The WIC program also exhibits a significant negative effect on expenditures for meals away from home. Unless WIC participation induces the purchase of expensive convenience foods, the results suggest that WIC increases the proportion of home cooked meals in the family diet.

Testing for Structural Change: The Demand for Meat

Seungmook Choi and Kim Sosin

Recent research on meat demand demonstrates the importance in empirical demand analyses of identifying and measuring structural changes. This paper develops and applies a method of analyzing structural changes in preferences using parameters from empirical demand equations derived from an underlying utility function. Structural changes alter the marginal rate of substitution between goods at fixed points of prices and quantities. The evolution of preference changes is measured by time-varying multiplicative terms in a translog utility function. The application to meat concludes that structural change occurred in the 1970s and provides measures of the time pattern of demand shifts.

Key words: beef demand, meat demand, preference change, structural change, translog function.

A serious challenge in empirical demand analysis is the identification and understanding of structural change. Assessing and testing for structural change is particularly critical in studies of disaggregated consumer goods demand with time-series data. Because it may not be appropriate to assume a stable utility function with consumers' perfect knowledge of the good, researchers typically use statistical methods to identify points of structural inconsistencies over the sample period. While such empirical methods are often useful, structural change parameters should emerge from the theory if possible.

In this paper, preference changes in consumer demand for meat are studied using an extension of a well-known production theory of disembodied technical change (Solow). Structural changes in preferences are represented by time-varying multiplicative terms within an underlying utility function. A desirable feature of the empirical system of demand equations derived from the utility function is that parameters are directly available to measure and test for structural change.

For the empirical implementation of this type of model, prior knowledge about the pattern of the structural change in production or demand is very important. Diamond, McFadden, and Rodriguez showed, in the context of production theory, that it is not possible to identify the effects of changes in technology and in factor prices on the demand for inputs, given usual economic data, without such knowledge. While technological change in production theory may not evolve smoothly over time, preference transformations by consumers based on social change or on additional information about the quality of goods do appear to follow a diffusion process. For example, the marketing literature has many theoretical and empirical studies using the logistic pattern of the time-path diffusion process to describe the adoption of new products by consumers. (e.g., Bass, Olsen and Choi). This paper introduces, in the context of a translog utility function, time-dependent parameters following patterns appropriate to structural change arising from the diffusion of information. Although specification problems are always possible when an assumed structure is used to test directly for structural change (Haidacher), careful employment of a flexible functional form with embedded testable time path functions for parameter change which arise from an optimizing model appears to provide empirically useful results.

The analysis developed in this paper is applied to structural change in the demand for meat. Recent studies have argued that the structure of meat preferences shifted significantly in the 1970s, characterized primarily by a decline in the demand for beef and other red meat. While new information about fat and cholesterol in the

Seungmook Choi is an assistant professor of economics, and Kim Sosin is an associate professor of economics, University of Nebraska, Omaha.

diet appears to be a major explanation, other suggestions have ranged from the effect on expectations of unprecedented economic shocks in the 1970s (Braschler) to social and economic changes associated with the women's movement (Rausser, Mundlak, and Johnson).[1] According to one argument, the demand for convenience foods has increased, but at the same time concern for health has skewed preferences away from red meat. Beef, historically the basic convenience meat, was particularly hard hit by the consumer push towards more healthful eating. The new popularity of chicken in restaurants, and the introduction of franchise chicken fast food chains and restaurants further illustrates this point (Thurman).

Following the literature review, a new theoretical base for the empirical testing of structural change is presented. In the subsequent section an empirical translog model of multiplicative structural change is constructed using this theory. The data description and test results are provided in the next section, followed by the conclusions.

Literature Review

The observed demand changes stimulated researchers to develop and test statistical procedures to identify and measure structural change. Rausser, Mundlak, and Johnson provide a general specification that embeds as special cases all of the parameter variation models used in the literature to that date, among them Cooley and Prescott (1973a, b), Belsey, Swamy, Singh et al., Goldfeld and Quandt, and the spline regression models of Poirier and of Buss and Lim. Among the statistical approaches applied to the meat demand problem are a Kalman filter to handle parameter changes (Chavas), a switching regression specification in an inverse demand model (Braschler), a Box-Cox transformation to estimate alternative specifications of demand (Moschini and Meilke), and a "least absolute value" technique to identify data shifts from outliers associated with structural change (Yanagida and Book). Other economists have studied the time patterns of consumer demand for meat (e.g., Wohlgenant and Hahn). The general, although not conclusive or unanimous, result of these studies is that a structural shift occurred in U.S. red meat preferences in the mid-1970s.[2]

Other researchers have emphasized the role of relative prices in the meat decline. Wohlgenant uses a seminonparametric method specifying a Fourier flexible functional form. Although his major conclusion is that mid-1970s shifts in demand for beef stem from changes in relative prices of beef and poultry rather than preference changes, he also finds that beef demand became more sensitive to poultry prices and that the relationship between beef and fish changed from substitutability to complementarity. Also, Martin and Porter identify relative price changes as the major cause of consumer demand changes in Australia but detect some structural change.

A different approach, based on a nonparametric test for structural change, was used by Chalfant and Alston. Their meat consumption data appear to satisfy the strong axiom of revealed preference. Although the power of such tests is uncertain, their work suggests that the data are consistent with utility maximization and therefore a stable utility function. The parametric approaches cannot rule out the possibility of a false rejection of the null of stability because of model misspecification; however, the wide variety of approaches and flexible form specifications finding structural change suggest that at least this question is open to further study.

Multiplicative Structural Change in Consumer Demand Theory

Hypothesis tests for structural change in consumer demand have not typically been based upon parameters derived from the utility maximization principle. Most studies have proceeded by direct parameterization of theoretical variables such as price elasticities and income elasticities, followed by examination of the stability of those parameters. However, differences in price and income elasticities do not necessarily imply structural change. It is unlikely that these parameters, even from a given preference structure, would be consistent across two time pe-

[1] For example, a midwestern newspaper recently referred to "a yuppie aversion to red meat" (*Omaha World Herald*, "For First Time, Poultry Takes Lead Over Beef," 3 Jan. 1988). Also Chalfant and Alston report that it is "widely suggested in industry circles that this reflects a shift in consumer preferences due to dietary concerns" and has been the impetus for developing new grading systems for beef (p. 395).

[2] One study whose empirical finding is contrary to structural change (Moschini and Meilke) uses the Box-Cox transformation. Although this parametric approach has the advantage of using a flexible specification, this flexibility also raises some questions. First, no criteria are presented for deciding which of the parameters are to be shifted. Second, flexibility may result in a high degree of fit at the expense of theoretical regularity conditions, which cannot be checked.

riods if other economic variables vary; that is, if the price ratios or the income levels between the two periods are different, the elasticities are likely to be different with or without a structural shift. An appropriate comparison of elasticities must be done at a fixed data point of prices and income levels, which is almost impossible with the usual model specification in the literature.

Suppose that the source of structural change in demand is a change in information held by consumers about the characteristics or attributes of goods. As consumers' information about goods' attributes changes, the resulting rearrangement of preferences generates a shift in the marginal rates of substitution at given points in the consumption space.

This type of structural change can be described conveniently by extending the framework of the specification of disembodied technical change in growth models. Let $x = (x_1, x_2, \ldots, x_n)$ be the quantity vector of goods in nonnegative orthant n-dimensional Euclidean space x, and let $q(t) = (q_1(t), q_2(t), \ldots, q_n(t))$ be the vector such that $q_i(t) = a_i(t)x_i$ for all i, where the $a_i(t)$ are nonnegative functions of time.[3] Call q_i the information-augmented quantity (IAQ) of good x_i. A natural interpretation is that, given fixed actual quantities of x_i, consumers' perceived IAQ or q_i changes by time-dependent scaling parameters. For red meat consumption, for example, as consumers realize the potential danger of cholesterol, a pound of red meat takes on a different implied weight of red meat consumption, so that $a_i(t)$ [and thus $q_i(t)$] change for given x_i. Conversely, if the consumers' decision is based on q rather than observed market goods x, consuming the same amount of q_i over time necessarily implies a change in market purchases of x_i with the time-varying parameter $a_i(t)$.

We assume that a representative consumer has a stable preference structure over the information augmented goods; that is, the preference defined over the IAQ space Q is time-invariant. However, preferences for the actual quantity of goods X may be changing over time. Therefore the consumer's utility function u_t at time t, defined on X, may be written as

$$u = u_t(x) = U(q_t),$$

where

$$(1) \quad q_t = (a_1(t)x_{1t}, a_2(t)x_{2t}, \ldots, a_n(t)x_{nt}).$$

The functional form of $a_i(t)$ characterizes how the change in technology or preference is processed on good x_i. We define a preference change as multiplicative if a vector $(a_1(t), a_2(t), \ldots, a_n(t))$ of functions exists that satisfies (1) such that $a_i(t) > 0$ for all i and t. It is not difficult to show that if a preference change is multiplicative, and if one of u_t or U satisfies the standard regularity conditions such as quasi-concavity and monotonicity in its own argument space, then the other will do so also for a given t.[4] Note that equation (1) is identical to the disembodied technological change specification in production theory.

An empirical model for testing the hypothesis of structural change should permit a comparison of theoretical parameters at a given data point. However, in some cases a change in preference may affect demand yet not alter the values of elasticities at a single data point. An example can be drawn from a CES utility function, in which the elasticities of substitution are constant for all data points even if the values of other parameters are changed. However, in general, a change in demand from any preference change should affect the marginal rate of substitution (MRS) at a data point.[5] Indeed, if a structural change is multiplicative, the MRS between goods in X is never constant as t changes except for a

[3] The transformation of x into q may be viewed as similar to the transformation of market goods into "characteristics" or "attributes" of Becker and Lancaster, to the extent that preferences defined on the consumption characteristics (IAQ) are stable, and structural change need not imply changes in preferences for the transformed consumption characteristics from market goods. However, the transformed variables, q_i, from using the multiplicative terms do not generate the unique characteristics in the Becker and Lancaster sense.

[4] If a preference change is multiplicative, then the regularity conditions of u_t on x are preserved in its transformed space Q and vice versa. It is trivial to show the preservation of monotonicity. Proof of the preservation of quasi-concavity: Let u_t be quasi-concave. Then, for two distinct bundles, x^0 and x^1 such that $u_t(x^0) > u_t(x^1)$, and for a real number λ such that $0 < \lambda < 1$,

$$u_t(\lambda x^0 + (1-\lambda)x^1) > u_t(x^1).$$

Let $q^0 = A_t \cdot x^0$ and $q^1 = A_t \cdot x^1$. Then, $u_t(x^0) > u_t(x^1)$ implies $U(q^0) > U(q^1)$ by definition. And

$$\begin{aligned} u_t[\lambda x^0 + (1-\lambda)x^1] &= U[\lambda A_t x^0 + (1-\lambda)A_t x^1] \\ &= U[\lambda q^0 + (1-\lambda)q^1] \\ &> u_t(x^1), \\ &= U(q^1). \end{aligned}$$

Thus,

$$U[\lambda q^0 + (1-\lambda)q^1] > U(q^1).$$

The converse can be proved easily by a similar method.

[5] For a two-commodity CES production function

$$U = A(\delta x_1^{-\rho}) + (1-\delta)x_2^{-\rho})^{-1/\rho},$$

the elasticity of substitution between x_1 and x_2 is $1/(1+\rho)$. Therefore, a change in the value of δ will not alter the elasticity but will alter the value of the marginal rate of substitution at a given data point. Of course, a monotonic transformation of the utility function is not considered a type of preference change.

special case that is negligible in empirical demand analysis. Of course, with fixed preferences, the MRS also changes with an altered price ratio. To avoid the identification problems raised by Diamond, McFadden, and Rodriguez, the empirical specification must be able to separate the effects on MRS of price changes from preference changes. To do so, the multiplicative model in our specification imposes a flexible and reasonable pattern of evolving or declining preferences with eventual upper or lower limits on $a_i(t)$.

The magnitude and direction of the change in MRS between goods in X over time can be examined from the first partial derivative of the MRS with respect to time t, or equivalently, with respect to a_j.

Let the MRS between q_j and q_i be written

$$-(\partial q_i/\partial q_j) = (MU_{q_j}/MU_{q_i}) = f(q_1, q_2, \ldots, q_n),$$

where MU denotes marginal utility. But for any given t,

$$-(\partial q_i/\partial q_j) = -\frac{a_i}{a_j}\frac{\partial x_i}{\partial x_j}.$$

Thus,

$$(2) \quad -(\partial x_i/\partial x_j) = (a_j/a_i)f(q_1, q_2, \ldots, q_n).$$

Taking the partial derivative of (2) with respect to a_j to identify changes in MRS over time, we obtain

$$(3) \quad \frac{\partial[(a_j/a_i)f(q_1, q_2, \ldots, q_n)]}{\partial a_j} = (1/a_i)f(q_1, q_2, \ldots, q_n) + \frac{a_j}{a_i}\frac{\partial f(q_1, q_2, \ldots, q_n)}{\partial a_j}$$
$$= (1/a_i)f(q_1, q_2, \ldots, q_n) + \frac{q_j}{a_i}\frac{\partial f(q_1, q_2, \ldots, q_n)}{\partial q_j}.$$

Further implications of (3) for structural change can be easily described. A nonzero value for equation (3) indicates a change in the MRS between good x_j and x_i at one data point in consumption space X, therefore a structural shift in demand. The value of (3) can be positive, negative, or zero, depending on the elasticity of substitution and other features of the utility function.

For illustration, consider a constant elasticity of substitution (CES) form of the utility function, where x_i and x_j are the two goods. Given the value of the elasticity of substitution, the demand for x_j is shown to be decreasing or increasing by the value of $a_j(t)$. If the elasticity of substitution is less than (greater than) one, then the value of equation (3) is negative (positive).[6] When equation (3) is negative (positive), the demand for x_j is decreased (increased) as $a_j(t)$ increases over t, given fixed income and prices. The MRS between i and j would also change with a new a_k, for $k \neq i, j$, unless goods i and j are block-wise separable from the bundle of goods containing the kth good. Given separability, equation (2) is independent from q_k, and so is a_k, by definition of separability (Blackorby, Primont, and Russell).

A potential problem in measuring structural change is created for the empirical model if the value of (3) is zero. The Cobb-Douglas utility function is the only case for which the value of equation (3) is zero under multiplicative structural shift for any given positive real number a_i.[7] Because a Cobb-Douglas utility function is unlikely, this is not a serious problem for our test. If the utility function is Cobb-Douglas, then multiplicative structural change is merely a form of monotonic transformation and will not be identified as structural change. This is the analog in demand theory of the well-known growth theory result that if a production function is of Cobb-Douglas form, then disembodied technical progress does not affect the ratio of factor combinations.

The Empirical Translog Model

Empirical demand systems are usually derived from indirect utility specifications. Many existing flexible functional forms could be transformed into empirical models incorporating multiplicative structural change. We have cho-

[6] Let the CES function be

$$U = A(\delta q_1^{-\rho} + (1-\delta)q_2^{-\rho})^{-1/\rho};$$

where $q_1 = a_1x_1$ and $q_2 = a_2x_2$. Then,

$$f(q_1, q_2) = \left(\frac{\delta}{1-\delta}\right)\left(\frac{q_2}{q_1}\right)^{(1+\rho)}.$$

If $\rho > 0$, then $\sigma < 1$ and equation (3) > 0. If $-1 < \rho < 0$, then $\sigma > 1$, and equation (3) <0.

[7] An appendix showing that the Cobb-Douglas utility function is the only case for which the value of equation (3) is zero under multiplicative structural shift for any given positive real number a_i is available from the authors upon request.

sen the translog specification for its simplicity and popularity. A convenient feature of multiplicative structural change is that the functional structure is preserved from the direct utility function to the indirect utility function.

Consider the following utility maximization problem for time t:

$$(4) \qquad \text{Max } U_t(x_{1t}, x_{2t}, \ldots, x_{nt}), \quad \text{subject to } \sum_i p_{it}x_{it} = m_t,$$

where p_{it} is the price of good i at time t, and m_t is total expenditure at time t. If the preference change is multiplicative, then the maximization of (4) is mathematically equivalent to the following problem:

$$(5) \qquad \text{Max } U(q_{1t}, q_{2t}, \ldots, q_{nt}), \quad \text{subject to } \sum_i z_{it}q_{it} = m_t,$$

where $z_{it} = p_{it}/a_i(t)$ and $q_{it} = a_i(t)x_{it}$. The subscript t of U in (5) is deleted because the utility function is assumed to be stable on IAQ space. Following Christensen, Jorgenson, and Lau, the indirect utility function dual to the utility function (5) is of the form

$$V = v(z_{1t}/m_t, z_{2t}/m_t, \ldots, z_{nt}/m_t) = V(b_1(t)p'_{1t}, b_2(t)p'_{2t}, \ldots, b_n(t)p'_{nt}),$$

where $b_i(t) = 1/a_i(t)$ and $p'_{it} = p_{it}/m_t$. In terms of the model employed for this study, the translog specification of the indirect utility function defined over the transformed z_i vector space is

$$(6) \quad \text{Log } V = c_O + \sum_i c_i(\log(z_i/m) + (1/2)\sum_i\sum_j c_{ij}(\log(z_i/m)(\log(z_j/m)),$$

where time subscript t is omitted for notational simplicity. Applying modified Roy's identity, the following share equations are obtained:

$$(7) \quad \frac{z_iq_i}{m} = \frac{c_i + \sum_j c_{ij}(\log(z_j/m))}{\sum_k c_k + \sum_k\sum_j c_{kj}(\log(z_j/m))},$$

for all i, or

$$(8) \quad \omega_i = \frac{p_ix_i}{m} = \frac{c_i^* + \sum_j c_{ij}(\log(p_j/m))}{\sum_k c_k^* + \sum_k\sum_j c_{kj}(\log(p_j/m))},$$

for all i.

where $c_i^* = c_i + \Sigma_j c_{ij}\log(b_j(t))$. The value share equations (8) are identical to those derived from the usual translog indirect utility function if $b_j(t) = 1$ for all j and t. With the appropriate specification of $b_j(t)$, the testing of structural change in the translog equation (8) is equivalent to checking the statistical consistency of the first-order terms, c_i^*, over the sample period.

The next step in the empirical specification of the multiplicative preference change model is to choose a $b_j(t)$ function that facilitates an appropriate pattern of structural change. While many specifications are possible, we introduce two convenient one-parameter relationships, the step function and the smooth logistic function.

Step Function

Often a structural shift is assumed to occur at a particular time when new information becomes available and preferences change. Hence the sample is divided into before and after subsets, with estimation applied to each sample period and to the whole period. The null hypothesis of equality of coefficients across the subperiods is accepted or rejected by a comparison of the sums of the squared residuals. In contrast, for the multiplicative structural change case, a preference shift with this before and after pattern can be specified within the model by choosing a step function for $b_j(t)$.

$$b_i(t) = 1 \text{ if } t < t_0$$
$$b_i(t) = \exp(\beta_i) \text{ if } t \geq t_0,$$

where t_0 is the date when the structural change is believed to have begun. If $\beta_i = 0$, then $b_i(t) = 1$ for all i, and the share equations are those of the simple translog function. Thus, a test of the null hypotheses $\beta_i = 0$ is equivalent to a test of no structural change for good i; if β_i is significantly different than 0, the null hypothesis of no structural change is rejected. The direction of the shift is shown by the sign of β_i. If β_i is less than (more than) 0, then $b_i(t)$ is a decreasing (increasing) function of t.

Smooth Function

Rather than a sudden step of the preference structure at a given time, preferences may exhibit a smooth evolution throughout the sample period. In this case, $b_i(t)$ should be specified as continuous in t and have an arbitrary upper and lower limit as $t \rightarrow \infty$. In addition, to maintain degrees of freedom, it is desirable (although not necessary) to again choose a function for $b_i(t)$ with only one parameter. For these reasons, the logistic function is an ideal choice:

$$b_i(t) = 1/(1 + \exp(\beta_i t)).$$

In this function, if $\beta_i = 0$, then $b_i(t) = 1/2$ for all t and i. Thus, equation (8) does not collapse to the original translog share equations when $\beta_i = 0$. However, because of the nature of the value share equations, for statistical inference purposes a constant $b_i(t)$ will make equation (8) equivalent to the original equations. When $\beta_i = 0$ is imposed and $b_i(t)$ is unvarying, the constants c_1 and c_2 can be arbitrarily determined by the fixed values of the second-order terms of the translog specification. Therefore, like the case of the step function, if β_i is significantly different from zero, the null hypothesis of structural change will be rejected. In fact, there will be no difference in any statistical result—for example the sum of squared residuals or t-ratios of parameter estimates—between the original translog equation and equation (8) with $\beta_i = 0$ imposed. Note that if β_i is greater than (less than) zero then $b_i(t)$ is a decreasing (increasing) function of time t.

The use of the logistic function to study structural change in consumer demand is most appropriate when new or revised information is the major source of structural change. The theoretical discussion of and empirical application of the logistic function can be found in the literature on new product growth based on time-diffused information (Bass, Olsen and Choi).

Data and Estimation

The above variations of the translog model were applied to the demand for food in the United States, using three food items, red meat, poultry, and other foods (hereafter denoted by subscripts 1, 2, and 3), such that total expenditure on these items is equal to total consumption of food. The choice of these three goods can be rationalized by the usual assumption of separability of preferences; that is, assume that these three goods are separable from other goods in consumers' preferences. Beef was not separated from other red meat because, first, consumer health concerns may apply to the entire red meat category and, second, a consequence of adding another good is a large loss of degrees of freedom from additional parameters associated with the translog and the structural change functions. Annual time-series per-capita indexes from 1953 through 1984 covering retail quantities for red meat, poultry, and other food ("all food" less red meat and poultry) were obtained from *Food Consumption, Prices, and Expenditure*, and *U.S. Food Consumption Sources of Data and Trends* (USDA).[8]

The full information maximum likelihood estimation technique was applied to equation (8) for estimation of the parameters, with additive disturbance terms assumed contemporaneously correlated.[9] With the additive disturbance specification, it is well-known that the contemporaneous variance-covariance matrix of disturbances does not possess full rank. Barton and Theil (1976, 1971) showed that the rank is the number of goods in the system of demand equations less one. The maximum likelihood estimates are invariant to the equation deleted, which was the demand equation for other foods in this study. The usual normalization for identification of the models and the symmetry are imposed by setting $\Sigma_i c_i = -1$ and $c_{ij} = c_{ji}$ for all i and j, respectively. The starting values for coefficients were obtained from nonlinear OLS estimates of the system.

Equation (8) with additive disturbance terms was estimated several times: first, for no structural change [$b_i(t) = 1$ for all i]; second, for the step function; and, third, for the logistic function. To illustrate the step function we assume that information change affects red meat only, that is, for red meat, $b_1(t) = \exp(\beta)$ but $b_i(t) = 1$ for $i = 2, 3$. Based on previous work suggesting that structural change began in the mid-1970s, $t_0 = 1974$ is assumed to be the critical time period of the shift of preference structure (e.g., Braschler). The step data cannot be tested directly, but if the step function was deemed appropriate for structural change in a particular application, it could be estimated with each pos-

[8] Expenditures in 1967 for each item were used, with the retail weight quantity indexes based at 1967, to construct constant 1967 dollar values of quantity of retail meat. Price indexes were also normalized to 1967. We thank Howard Elitzok of the USDA for providing the data.

[9] The GRG2 Fortran nonlinear programming package developed by Leon Lasdon at the University of Texas at Austin was used.

sible date as the step date, and the likelihood values compared.

For the logistic function, three cases are analyzed, each implying a different impact of information change on food demand. Although it is believed that the information change had its primary impact on red meat demand, this assumption is imposed on only the first case. Accordingly, for the first logistic function case, $b_2(t)$ and $b_3(t)$ are set equal to 1, for the second case, only $b_3(t)$ is set equal to 1, and finally, no $b_i(t)$ coefficient is assumed to be 1 so that all are determined by the estimation. For all cases, the form $b_i(t) = 1/(1 + \exp(\beta_i(t - t^*))$ is used, where t^* is the middle data point. The purpose of introducing t^* is to minimize possible rounding errors in the computation.

Both the t-test and likelihood ratio test procedure were executed on the hypotheses.[10] It is well known that twice the difference of the log-likelihood values between unrestricted and restricted parameter spaces ($2 \log \lambda$) is asymptotically chi-square distributed with q degrees of freedom, where q is the number of restrictions imposed on the parameter space.

[10] The asymtotic standard errors for the t-statistics were obtained by inverting the information matrix evaluated at the parameter estimates. This requires that the second-order derivatives of the log-likelihood function be computed numerically (e.g., $\Delta \log L(c))/\Delta c^2$, where Δ is the difference operator and c is a parameter value), in which case the value of the second-order derivatives may be very sensitive to the choice of Δc. In our estimation, we have used $\Delta c = c^* \cdot 0.00025$, where c^* is the maximum likelihood estimate. Our experience was that 0.00025 is small enough relative to the parameter estimates for the numerical derivatives. Also, we tried other small values with no significant change in computed t-values. However, in the likelihood ratio test, this problem can be avoided.

Empirical Results

Tables 1 and 2, and figure 1 present the results of the estimation. Table 1 displays the parameter estimates for the three cases—no structural change (model 1), abrupt structural change (step function model labelled 2-1), and evolutionary structural change (logistic function models 2-2, 2-3, 2-4). For the logistic function, the three versions described earlier are shown: $i = 1$, $i = 1, 2$, and $i = 1, 2, 3$ for models labelled 2-2, 2-3, and 2-4, respectively. The percent violation row in table 1 indicates the percent of the data points that violate theoretical conditions. At each data point, monotonicity was checked by evaluating the sign of the predicted value share, where a negative value implies violation, and the quasi-convexity requirement on V was checked by examining if the estimated matrix of the elasticities of substitution is negative semidefinite (Caves and Christensen). Also indicated for each func-

tion are the value of the log likelihood function, and the implied percent change from 1970 to 1984 in per capita red meat consumption, given fixed 1974 income and prices.

By all standards, the multiplicative change logistic function of model 2 is preferred, further, the results of the t-test procedure and percent violation test indicate that models 2-2 and 2-3 provide an excellent fit with few points of violation. The t-test and loglikelihood ratio statistics for the null hypothesis that $\beta_1 = 0$ support the occurrence of structural change in red meat consumption. The estimated decline in per capita red meat consumption is similar, −13.5% in model 2-2 and −11.2% in model 2-3.

An alternative model was also estimated to test for structural change (Diewert and Wales; Ewis and Fisher). This model uses a flexible functional form and time t as a function argument for technological change. In this model time is usually used as an explicit argument in the expression for technological change when the true technological index is unknown and a change in technology is suspected. It appears to be general, but with a translog function it is equivalent to a particular multiplicative structural change specification that may be unduly restrictive.[11] A test of this approach yields inferior results for the log-likelihood value and for coefficient significance compared to multiplicative structural change, and over 95% of the data points violate regularity conditions.

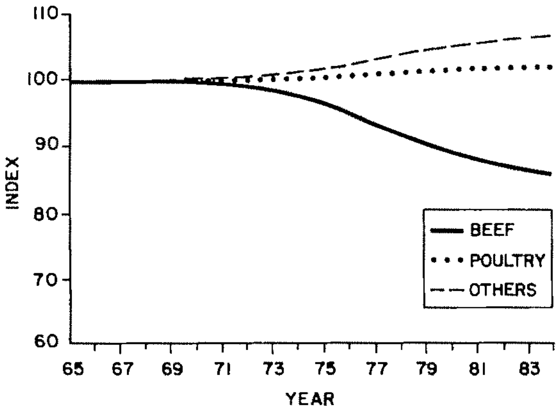

Figure 1. Predicted consumption quantity indexes

The logistic function model 2-2 was used to generate predicted annual consumption quantity indexes, normalized at 1965 = 100, for given income and prices fixed at 1974 levels. The plotted indexes, shown in figure 1, are a dramatic illustration of the impact of structural change on red meat demand. If consumers be-

[11] Given the unknown true indirect utility function whose argument includes time T, $V = V(p'_1, p'_2, \ldots, p'_m, T)$, the second-order Taylor series approximation in logarithms yields

$$\begin{aligned} \text{Log } v = a_0 &+ \textstyle\sum_i a_i(\log(p_i/m) \\ &+ (1/2) \textstyle\sum_i \sum_j a_{ij}(\log(p_i/m)(\log(p_j/m)) + a_T \log T \\ &+ 1/2 \textstyle\sum_i a_{iT}(\log(p_i/m))(\log T) + 1/2\, a_T(\log T)^2. \end{aligned}$$

Applying Roy's identity:

$$\omega_i = \frac{a_i^* + \sum_i a_{ij}(\log(p_j/m))}{\sum_k a_k^* + \sum_k \sum_j a_{kj}(\log(p_j/m))} \text{ for all } i,$$

where $a_i^* = a_i + a_{iT} \log T$ for all i. Hypothesis testing for structural change is the same as testing if a_{iT} is significantly different from zero for all i. This is equivalent to the multiplicative structural change specification of power function $b_j(t) = T^{a}jT$. A restriction is that the process converges only if a_{jT} is less than zero.

came cognizant of the impact of fat and cholesterol on health over the period from 1970 to 1984, these and other concerns appear to have caused the per capita red meat consumption index to drop by over 10% for given prices and incomes. Earlier studies had suggested, and the logistics model confirms (fig. 1), that the decline in red meat consumption was activated at about 1974, a timing result that was not imposed on this model.

Table 2 provides estimates of the elasticity parameters from each equation for red meat, poultry, and other foods. The elasticities represent an average over the data points for the sample time period. The π_{ij} are Marshallian cross-price elasticities of demand for good i with respect to j, and the η_i are income elasticities for good i. All elasticities look reasonable in sign, even for those models with violation of utility maximization conditions for 95%–100% of the data points. Clearly a set of appropriate signs for the elasticities is not enough evidence to conclude that the model is appropriate.

A word of caution is in order. As stated earlier, based on their nonparametric results, Chalfant and Alston do not reject the existence of a stable utility function. If their conclusion is correct, our results may imply inflexibility of the translog function. However, we found that introducing one multiplicative term on meat only satisfies the regularity conditions at all data points but one. The monotonically decreasing scaling parameter $b_1(t)$ causes the indifference curve of the translog utility function defined on consumption space x to rotate in one direction constantly over the sample period. A substantial improvement of the regularity conditions by such rotation of the indifference curves over the thirty-two-year time span suggests that a smooth preference change has occurred.

Conclusions

This paper introduces a method with roots in technological change theory for identifying, measuring, and testing for structural change in the preferences of consumers. The method proves useful in identifying structural change in red meat demand in the mid-1970s in the United States. Structural change is specified as a time-varying multiplicative term within an underlying consumer utility function. The translog flexible functional form specification for the underlying utility function is used to develop the equations for estimation, which incorporate first a step function, and then a smooth logistic function as the multiplicative term.

Although any parametric approach is subject to misspecification, multiplicative structural change offers several advantages. First, empirical tests are directly based on parameters derived from microeconomic theory, unlike the usual procedure of relying on purely statistical approaches. Second, a wide variety of patterns of structural change can be measured, based on a judicious choice of functional form for the multiplicative term.

In the application to meat demand, the empirical model with multiplicative structural change produced improved statistics of fit compared to the case of no structural change, and to the alternative approach used by Diewert and Wales and by Ewis and Fisher. Although all estimations yield reasonable signs for all prices and income elasticities, the assumptions of monotonicity and quasi-convexity are violated in over 95% of the data points in the models of no structural change and the alternative approach. These problems are not present in the logistic function models. Estimations of the logistic function models support the existence of structural decline in U.S. red meat demand since the early 1970s.

Comment and Reply

An Inverse Demand System for U.S. Composite Foods: A Comment

Trevor Young

In a recent article in this *Journal*, Huang summarized the theoretical basis of inverse demand systems and estimated a set of price flexibilities for U.S. aggregate food groups. Following Anderson, attention focused on the theoretical constraints on compensated and uncompensated flexibilities. These constraints are analogous to the familiar "general restrictions" of standard demand theory—homogeneity, Cournot aggregation, Engel aggregation, and Slutsky relations. However, Huang neglected to record another aspect of the dual nature of inverse and quantity-dependent demand systems, the property, demonstrated by a number of authors including Anderson and Houck, that the matrix of price elasticities can be derived by inverting the matrix of flexibilities. This duality is important to note because it provides a link between inverse and "direct" demand systems and so allows all the elasticities and flexibilities to be computed, given the values of budget shares, once either set of parameter values has been estimated. Moreover, the derivation of elasticities provides an additional check on whether estimates obtained from an inverse demand system accord with a priori reasoning. It is the purpose of this note to demonstrate that when this additional computation is performed on Huang's model, the validity of his results is brought into question.

Huang presented the set of estimated compensated flexibilities (f_{ij}^*) for thirteen food products and a nonfood aggregate, together with their respective budget weights (w_i), and the scale flexibilities (g_i). (A hint that something may be amiss in the model is given by the positive, albeit statistically insignificant, own-quantity compensated flexibility for fish.) From this information, the uncompensated flexibilities (f_{ij}) are obtained as follows:

$$f_{ij} = f_{ij}^* + g_i w_j.$$

Assuming the matrix of these flexibilities ($F = \{f_{ij}\}$) is invertible, then the matrix of price elasticities ($E = \{e_{ij}\}$) is computed as

$$E = F^{-1}.$$

Using the homogeneity condition, income elasticities (η_i) are given by

$$\eta_i = -\sum_j e_{ij}.$$

Finally, the compensated elasticities (e_{ij}^*) can be retrieved from

$$e_{ij}^* = e_{ij} + \eta_i w_j.$$

These computations, when based on the econometric estimates of compensated flexibilities reported by Huang, provide the elasticity estimates recorded in table 1; to save space only own-price and income elasticities are presented. The unacceptable nature of these results is immediately clear. Five of the compensated price elasticities (fish, dairy, fats, fruits, non-food) violate the "law of demand," given that a fundamental property of the (negative semidefinite) Slutsky matrix is that its diagonal elements must be nonpositive. These perverse results carry over, in four cases, to the uncompensated forms of the own-price elasticities. It would therefore be concluded that either the bias in aggregation has been so great that the theoretical restrictions do not hold at the market level, or the constraints are indeed valid but the model has been misspecified in some way. In any event, if these additional computations had been undertaken, it is doubtful whether the researcher would have been as satisfied with the analysis.

An Inverse Demand System for U.S. Composite Foods: Reply

Kuo S. Huang

In his comment, Young attempted to verify Huang's empirical inverse demand system by first deriving an uncompensated price flexibility matrix from Huang's compensated price flexibility estimates and then inverting the derived uncompensated price flexibility matrix to obtain what he claimed to be a demand elasticity matrix. The approach he uses for verification, however, is conceptually and empirically inadequate.

First, Hicks has systematically treated the inverse demand and defined "q-complements" and "q-substitutes" of the Antonelli matrix in contrast to the "p-complements" and "p-substitutes" of the well-known Slutsky matrix in ordinary demand. As shown in Deaton and Muellbauer (p. 57), the Antonelli matrix and Slutsky matrix are closely linked; they are generalized inverses of each other. Conceptually, if one intends to verify the dual nature of a demand system, one should focus on the generalized inverse relationships between the Antonelli and Slutsky matrices rather than using Young's intuitive approach by comparing the estimated price flexibilities with the derived demand elasticities. Moreover, Young's demand elasticity matrix is derived from a constructed uncompensated price flexibility matrix that departs from the functional form specified in Huang's inverse demand system. I know of no theoretical basis to verify the inverse demand system by using Young's derived demand elasticity matrix that is obviously outside the framework of the initial model specification for the inverse demand system.

Second, in general, the empirical demand elasticity and price flexibility matrices obtained from certain well-known estimation procedures are not the reciprocal of one another in a statistical sense because the two sets of regression lines differ from one another. In an ordinary demand system, the sum of residuals is minimized along the quantity axis; whereas, the sum of residuals is minimized along the price axis in an inverse demand system. The problem was discussed in Houck, who summarized some earlier studies and concluded: (a) the reciprocal of the direct price flexibility is not in general the same as the direct price elasticity, and (b) the reciprocal of the price flexibility is absolutely less than the true elasticity if there are discernible cross effects with other commodities. Thus, Young's demand elasticity matrix, which is computed as the reciprocal of a derived uncompensated price flexibility matrix, has limited practical use because the elasticity matrix may not represent the "true" demand structure as reflected from the sample observations. Perhaps a statement from Waugh (pp. 29–30) best addresses this point: "I prefer to use the price flexibilities themselves rather than their reciprocals. If, for any reason, the elasticity of demand is wanted, I would prefer to use the other regression equations, using quantities as the dependent variables."

Third, there are at least two additional drawbacks in Young's effort to obtain a matrix of demand elasticities by inverting a derived uncompensated price flexibility matrix. One drawback relates to ignoring the stochastic properties of point estimates for Huang's compensated price flexibilities, which are subject to certain probability distributions with means and variances. In his inversion process, Young treats the point estimates as pure numbers representing the true parameters but ignores the associated variance. It becomes apparent that Young only partially considers the stochastic nature of Huang's estimates. Another drawback is that the inverted results are quite sensitive to the numerical structure of the matrix being inverted. We should be aware that the potential problem of singularity or near singularity in such a big matrix (14 x 14 in our case) is likely to cause the inverted results to be quite unstable. In those cases. one might question whether the derived demand elasticity matrix is able to provide any meaningful economic information, let alone serve as a basis for verifying the counterpart of the inverse demand system.

Books Reviewed

Alexandratos, Nikos, ed. *World Agriculture Toward 2000: An FAO Study*. New York: New York University Press, 1988, xx + 338, pp., $55.00.

This is a book prepared by a team led by Nikos Alexandratos, chief, Global Perspectives Studies Unit of the Food and Agriculture Organization (FAO). The book opens with a preface by Eduardo Saouma, director general of FAO. He explains the intent and the purpose of the book as follows: "It analyzes and as far as possible quantifies major changes likely to emerge in world agriculture, forestry and fisheries by the end of the century. . . . The study analyses and presents options for policy measures needed to meet the dual challenge of ensuring adequate supply and of improving access to food by all" (pp. xi–xii).

The book is a revised and updated version of "Agriculture: Toward 2000" which was submitted to the 1979 Conference of FAO and the shorter version published in 1981. What future is in store for mankind by the year 2000? Are the projections favorable? Were the assumptions and methodology used in making the projections realistic? What are the recommendations and guidelines that may be implemented to change the course of events? The book answers some of these questions.

The book is divided into eleven chapters and four appendices. Chapters 1 to 6 deal specifically with food and agricultural demand and supply analyses and projections. Chapters 7 to 11 concentrate on policy issues. The appendices contain statistical tables of the simulation results. The first chapter provides an excellent summary of the objective, methodology, and the results of the study. The central conclusion of the study is one of guarded optimism. "The FAO believes that agricultural development can continue to the extent projected without seriously damaging the world's natural resources. This assessment however carries a proviso: That more weight be given to environmental requirements in development policies and expenditures" (p. 25).

Chapter 2 reviews what has happened in world agriculture in the past twenty-five years. The heart of the study is chapter 3, where the methodology, empirical investigations, and the results are analyzed. The projections of demand, production, and trade are carried out for each of the commodities and countries analyzed individually. Chapter 4 examines the conditions that must be satisfied if the annual growth rates are to be met. Chapters 5 and 6 deal with the outlook for forestry and fishery demand and supply balances in the year 2000. Chapters 7 to 11 deal with the macroeconomic adjustments and institutional arrangements needed to solve the world "food equation" problem. The focus is on the third world. The aim is to analyze feasible changes that need to be made for the developing nations to meet the supply projections under socially acceptable growth rate with equity and without destroying the environment. To this end, strategies to deal with the problems of rural poverty, growth and equity, and rural industrialization are analyzed. For example, there is a discussion of how to find ways and means to "promote technologies that increase or sustain productivity at lower cost and do not harm the environment" (p. 237). The study concludes with a chapter that deals with the environmental aspects of agricultural development.

This, perhaps, is the most important and useful book that we have in the field of "global futures studies," on food and agriculture. It can be used by planners from developing countries to help them set production targets. It can also be used as a textbook in agricultural economics courses at the graduate level. Given the nature and scope of the subject, there are a lot of issues one can raise and disagree with. These may range from methodology to interpretations of the results. On the whole, the book is well written. Issues are raised and discussed at a high level of rigor.

Some readers, including this reviewer, may feel that the FAO experts are too optimistic about the future and may want to disagree or raise some questions about some of conditions and recommendations. Will we see a better-fed world in the year 2000? The FAO experts give a condition that should be met: "The production projections of this study are founded on feasible changes in input usage and involve adaption and transfer of existing technologies across regions" (p. 231). In the case of Africa, the FAO experts do not feel that this condition will be met: "To ensure the spread of new, improved technologies there is a primary need for extension and manpower training services and to assure access to them by the small farmer and landless laborer. Yet these requirements have been neglected in many parts of the developing world notably in Africa" (p. 230). World population is projected to grow at 1.6% per annum between 1985 and 2000 to nearly 6.1 billion, of which 4.8 billion will be in developing countries (p. 72). The FAO analysis requires a 60% increase in agricultural production in developing countries and 20% in developing countries for the next fifteen years. Will the third world be able to grow at this rate, especially Africa?

The consequence of population growth on the economic development of the developing countries is not well understood. Some economists consider long-term projections as speculative exercises rather than forecasts: Kelley has argued that "they are fraught with uncertainty arising from difficulties in predicting fertility trends and the fact that forecast errors cumulate over time" (p. 1092).

The recommendations for the forestry sector reads:

"Actual needs for fuelwood in the year 2000 could exceed projected. . . . A tree planting rate of 7 million per year in developing market economies would be required to meet these needs" (p. 166). In the fisheries sector, it is estimated that "total demand for fish by the year 2000, assuming no changes in relative prices or in the use of fish for fish meal, might well exceed 100 million tonnes" (p. 179). FAO hopes that with proper management the world could meet the supply projection and other conditions. Some environmentalists who view agriculture as a threat to the ecosystem will certainly disagree with the FAO study.

Asian Productivity Organization. *Farm Finance and Agricultural Development.* Tokyo: Asian Productivity Organization, 1988, iv + 561 pp., price unknown.

This volume presents the proceedings of seminars held in Tokyo in 1985 and 1986 on farm credit. The main objective of the book is to disseminate findings and information generated in rural finance studies in Asia. The seminars included presentations and discussions of country statements, technical papers, and field studies addressing the state of Asia and Pacific rural credit, the role and performance of rural financial markets, mobilization of rural savings and default issues, as well as cross-country experiences and government credit policies. The book is organized in six major sections containing a total of thirty-one papers, and three appendices. Most of the contributors are scholars representing Asian Productivity Organization (APO) member countries, both the constituency and the intended audience of the volume. A few conceptual papers were prepared and presented by invited authors.

The volume succeeds in highlighting major issues in the region's financial markets, among others the need to foster deposit mobilization, to understand the importance of informal finance, and to better recognize the role of agricultural cooperatives in institutional lending. Loan recovery performance was singled out as the current most important concern, even though the section on default issues appears to be the weakest in the volume.

The key propositions of the so-called "new view" on rural finance are also well represented in the volume: (*a*) "Financial markets are vital in supporting development, but are largely ineffective when used to lead development efforts" (p. 37); in particular concessionary credit programs will not attain their intended goals while resulting in unintended and undesirable effects on the well being of the rural poor (*b*) Rural financial markets do not perform efficiently if agriculture is penalized through "low farm price and lack of investment in rural infrastructure" (p. 38) And (*c*) "rural financial markets work more efficiently, and certainly more equitably, when both lending and savings mobilization are emphasized" (p 38); indeed, rural savings are likely to increase substantially "if savings facilities are adequately provided in the rural areas" (p. 352). The need for appropriate financial policies and improvement of the overall quality of financial services provided in rural areas is the main corollary to the foregoing propositions.

In his paper Egaitsu draws a useful parallel between the "traditional" views on agricultural credit which the author labels the "farm finance" approach and the new "rural financial market" approach Egaitsu, along with Meliza Agabin and Tongroj Onchan, appropriately portray the limitations of the traditional approach in the region. Egaitsu and Agabin however. are more cautious in fully endorsing the new approach, their doubts apparently associated with the perceived presence of market imperfections in rural areas.

In addition to the conceptual papers indicated above Agabin's contribution on savings mobilization and Onchan's paper on farm credit policies are the highlights of this volume. The country studies, all essentially descriptive, vary rather widely in comprehensiveness and analytical quality. Most of the data reported are reasonably up to date, although the differing format makes cross-country comparisons difficult.

As a technical volume on rural finance and development, the book cannot compete with others, such as the volume edited by Adams, Graham, and Von Pischke or the recent textbook by Maxwell Fry However, the volume provides a useful discussion of key financial market issues in the region by highly qualified Asian scholars. The APO is thus successful in improving communications about rural finance problems among countries in the Asia-Pacific region Policy makers and donor agencies in the region will find this volume a useful reference.

Australian Bureau of Agriculture and Resource Economics. *Japanese Agricultural Policies.* Canberra: Australian Publishing Service, 1988, xiv + 359 pp., price unknown.

This book aims to fill an important void in the agricultural trade literature and does it quite well. Japanese agricultural policy is probably the least understood policy among high-income countries. This book provides a thorough description of the latest policy developments in Japan's agriculture and, in the process, reviews the most influential writings on the subject. The authors go beyond a cold definition of the policy instruments and integrate agriculture into the global economic system while taking into account the social and political contexts in which the Japanese agricultural policy has evolved. This kind of presentation makes the book more enjoyable to read and elevates it from a glorious collection of tables to an insightful document. The institutions are accurately portrayed as well as the regional realities of the country. In fact, while reading the book, one wonders how Japan's agricultural policy could be any different. The book is very effective in rationalizing the historical *cheminement* as well as the current state of the agricultural policy in Japan. This is undoubtedly the most important contribution of the book because it is hard to understand why the Japanese government and the Japanese people could tolerate such high levels of agricultural protection.

The book contains an extensive bibliography of almost everything ever written in connection with Japanese agricultural policy, including nonacademic publications. The work of experts on Japan's agricultural policy (e.g., Hayami, Hemmi, and Honma) is concisely summarized and is used to enrich the policy analysis subsections. The exposition is also enhanced by the numerous tables, figures, and maps used to support the discussion in the text. Every paragraph is summarized by small phrases beside the upper portion of the paragraphs.

The volume is divided into three main sections: (1) "Goals, Policy Instruments and Effects," (2) "Japan's Agriculture and Its Major Industries," and (3) "Issues in Adjustment." The first section is a broad description of Japan's agriculture. It is instructive but often appears repetitive. The discussion on protection does not differentiate trade-distorting subsidies from neutral subsidies and is restricted to the content of the corresponding tables. This is unfortunate because many potential readers are not trade experts. The first chapter in the second section should probably have been included in the first section. It is about the characteristics of Japan's agriculture and repeats many previously mentioned ideas. The remainder of the second section focuses on specific industries. The grain industries and the dairy, beef, sweetener, fruit, forest, and, finally, the fishing industries are extensively investigated.

Though the book covers a long list of topics, it is disappointing that an analysis or description of policies regarding pork imports is excluded. The Japanese market is very important for the United States, Canada, and Asian pork exporters and certainly deserves a few pages. Chapter 12 provides an accurate account of the problems between Japan, the United States, and the Soviet Union over fishing. However, its discussion of the Japanese fishing industries and environmental problems is rather limited. The last section of the book concentrates on the need for further reform and discusses how domestic programs and commercial policy should be altered to enhance the efficiency of the agricultural sector and minimize the repercussions on the international scene.

I strongly recommend this book as suggested reading for either undergraduate and graduate courses in agricultural trade policy. Its main advantage is its presentation. It is precise, clear, and very institutional in nature (perhaps at the expense of more thorough economic analysis). The findings of the most important papers and books on the subject have been incorporated in the various chapters in a manner conducive for learning. This book could easily be nicknamed "Handbook of Japanese Agricultural Policy," but it is clearly not a substitute for more technical books or articles.

Barnett, Tony. *Social and Economic Development—An Introduction.* New York: Guilford Press, 1989, viii + 232 pp., $35.00, hardback $16.95 paper.

Agricultural economists working on problems of economic development are frequently reminded of the social, cultural, and political factors that influence change in third world societies. In the search for greater understanding of these factors, we often turn to sociologists, anthropologists, historians, and political scientists for insights. Barnett's book promises to provide some of these insights. Barnett, a professor in the School of Development Studies at the University of East Anglia, concentrates his efforts in this book "on sociology rather than on policy or development because I believe that sociology, together with its related discipline, anthropology, provides valuable insights into the problems of development in the 'Third World' . . . and in the so-called 'developed countries' . . ." (p. vi.). His emphasis is clearly on sociology, although economics appears in the title and is referred to throughout the text.

The book was written as a textbook for first-year sociology students and for more advanced students interested in the topic. The book is divided into three parts, with a total of ten chapters. It also contains a forward by James C. Scott, a preface, an afterward, a glossary, a bibliography, and an index.

Part I consists of two chapters and provides an introduction to the roots of sociology, the contributions of important sociologists of development (Saint-Simon, Comte, Weber, Durkheim, etc.) and the con-

cepts and theories of development used by sociologists. Most agricultural economists will recognize the names and works of Karl Marx, Max Weber, Talcott Parsons, Walt Rostow, and David McClelland (*n* achievement) among others. Brief introductions to the concepts and theories of utopianism, social solidarity, social evolutionism, functionalism, modernization theory, capitalism, Marxist sociology, and world system theory are presented. Historical examples and contemporary situations are used to illustrate the concepts and theories.

Part II, entitled "Town and Countryside," contains two chapters on urbanization and industrialization, two chapters on rural development, plus one chapter each on the role of the state and gender issues in development. The thrust of the chapters on urban-industrial development is on the growth, specialization, and class systems that accompany such development. Readers are reminded that many of the largest cities of the world are in third world countries. The development of contemporary third world urban-industrial areas is explained from both the Marxist and modernization perspectives. Import substitution programs and export-oriented industrialization are seen as trapped in a web of dependency relationships, transnational corporations, and the internationalization of capital. Rapid economic growth in Brazil, South Korea, Taiwan, Hong Kong and Singapore "has been based on massive state interventions and on all kinds of special conditions which, it could be argued, cannot be replicated in other countries" (p. 90). The call for a new international economic order (NIEO) is seen as a failed effort, and the reader is left with the impression that there are no future successful paths of urban-industrial development for the third world. Apparently, economics is not the only dismal science.

The two chapters (5 and 6) on rural development may be of most interest to agricultural economists. The transition of the rural sector from primarily subsistence activities to production for the market is the principal topic of these chapters. The simultaneous presence of market and nonmarket relations is explained using two competing social theories: *substantivism* or the theory that people organize their production and distribution activities on the basis of unchanging values and moral beliefs and *formalism,* which in its extreme form holds that all of social life can be explained by economic theory. Although Barnett claims that some sociologists and anthropologists embrace the extreme form of formalism, most development economists would probably choose the middle ground between substantivism and formalism.

The transition from subsistence to market production is viewed as drawing the peasant into the broader national and world economy and creating a class structure comprised of landless laborers, poor peasants, and rich peasants. The green revolution and agribusiness transnationals are held responsible for the creation of the new class structure. Agricultural economists familiar with the literature on the gree revolution are not likely to accept Barnett's conden nation of the green revolution.

The third part of the book contains a chapter o defining and measuring development and a fin chapter that includes "case material" based on te readings and a series of questions. Much of the di cussion of the meaning and measurement of deve opment seems out of place and probably should hav been included in the first part of the book. An a tempt to distinguish between GNP and GDP is n clear (p. 179), and the Gini coefficient is mentione as a measure of income inequality without any re erence or explanation of how it is derived or inte preted (p. 179). In general, although there are ampl references to economic concepts throughout the boo they are not well explained nor adequately refe enced.

Overall, this book is not likely to provide muc that is new for agricultural economists who alread have a general knowledge of sociologists' and a thropologists' theories and studies of third world d velopment. For those looking for an introduction t the material, this concise book covers a broad rang of topics. It presents both the Marxists and no Marxists thought, and it does a good job in clarifyin the diversity among rural and urban populations i the third world. This latter contribution may offs some economists' proclivity to assume homogeneit in responses to and impacts of changing economi incentives. The chapter on gender and developme provides a good introduction to the important gend issues associated with economic and social deve opment. It is unfortunate that the book does not i clude more use of and reference to the literature o economic development. For example, the discussio of the process of agricultural-industrial transform tion does not include the normal economic explan tion based on Engel's laws.

One disturbing feature of the book is the excessiv uses of "boxes" to provide examples or elaborate o certain points. Although, I generally like this writin technique, much of the information contained in th boxes could have been incorporated in the text or p in footnotes. Finally, this book is not likely to b used as a text in agricultural economics courses. Som professors who teach undergraduate courses on ec nomic development may want to select a few cha ters for use as required or supplemental reading.

Roger Fox
University of Arizona

Coleman, David, and Trevor Young. ***Principles c Agricultural Economics: Markets and Prices i Less Developed Countries.*** **Cambridge: Cam bridge University Press, 1989, 323 pp., $69.5(**

The purpose of this book, according to the author is to equip its readers with the analytical tools an the theoretical basis for "solving the problems of ag

ricultural and rural development in poorer countries" (p. 2). It is one of the series of books developed by the University of London for its external postgraduate students in agricultural development. It deals with the principles, techniques, and applications of policy analysis in agricultural and rural development planning. It does an excellent job in its review of the basic economic principles and current theoretical issues and their relevance to the agricultural sector in the low income countries. The book is designed for use by teachers, students, and practitioners of the planning and management of agricultural and rural development.

To a significant degree, the book accomplishes its objectives. It is well written, organized, and appropriately sequenced. The book is organized around "the three main strands in the theoretical analysis of agricultural product markets—production, consumption and exchange" (p. 3). In each of these strands, the relevant economic theory and an excellent review of current theoretical debates are presented. These are generally followed by empirical applications and results presented in boxed illustrations.

The major strength of this book is its extensive review of economic theory in general and the synthesis of this theory to deal with policy issues in agricultural planning and rural development. This is best done in chapters 8, 9, 10, and 11. The discussions in these chapters are helped greatly by the empirical results and examples presented in boxed illustrations. This book is one of the few books that provides a good review of economic theory and discusses current and topical issues in third world agriculture and the practical dimensions to the analysis of agricultural policy in the less developed countries (LDCs). It does all of the above and yet pays attention to the practical limitations of the neoclassical economic theory in public policy decisions in the agricultural sectors of the LDCs.

The book has some limitations. One of the major weaknesses of this book is ironically related to one of its strengths mentioned above. In an attempt to review the major economic theory for the analysis of the agricultural sectors, exhaustive coverage of topics has been sacrificed for a broader review of theory. As a result, the analysis and discussions tend to be superficial and lack depth. For example, in the discussion of the marketing systems, the authors spend too much time discussing the competitive market structure, even though it has little relevance to the reality of the agricultural sector in most LDCs today. Instead, a detailed analysis and discussion of the side effects of imperfect markets and government interventionist policies in agriculture would have been more helpful to the practitioner of agricultural planning and rural development.

For a book designed for practitioners and policy makers, this volume is lacking when it comes to addressing some of the most critical issues facing the agricultural sector in the developing world today. For example, in discussing the determination of agricultural prices (chap. 9), the authors make no references or any serious attempt to discuss how agricultural prices in the LDCs are influenced by government interventionist policies. The authors assert that "prices farmers receive and the quantities they can sell are very much dependent upon the performance of firms above them in the marketing chains" (p. 19). In most LDCs, government policies such as price controls, concessionary interest rates, and input subsidies are important factors that influence price determination. Indeed, Mellor and Ahmed argue that "subsidy is treated as given at the time of formulation of product prices." Some of the critical and topical issues in the agricultural sector today in most LDCs, such as the effects on the agricultural sector of the World Bank-and the International Monetary Fund-supported structural adjustment programs, drought, technology transfer, and the environmental-production trade-off were not discussed at all in the book.

In chapter 11, while discussing trade theory, the authors fail to deal with trade barriers against agricultural products from the LDCs to the developed economies. No mention is made of the proposals contained in the "New Economic Order" that has been advocated by the LDCs to gain greater control in pricing their exports and playing a more active role in the world economy. It would have been appropriate and helpful if the authors had shown how these proposals would fit in with the neoclassical theory of international trade. The above weaknesses notwithstanding, I still find this book impressive. It is likely to be adopted by graduate agricultural economics programs, policy makers, and agricultural and rural development practitioners.

Mellor, John W., and Ahmed Raisuddin. *Agricultural Price Policy for Developing Countries*. Baltimore MD: Johns Hopkins University Press, 1988.

Compton, J. Lin. *The Transformation of International Agriculture Research and Development*. Boulder, CO: Lynne Rienner Publishers, 1989, xi + 237 pp., $30.00.

This book was commissioned by the Experiment Station Committee on Organization Policy (ESCOP) of the National Association of State Universities and Land Grant Colleges (NASULGC) as part of the centennial celebration of the Hatch Act of 1887, which funds state agricultural experiment stations. It assesses the "transformation of the nature and functions of agricultural research and development institutions and their programs, describes the major changes, and identifies key trends and issues. It also documents the influence of U.S. initiatives on agricultural development and the relative effectiveness and efficiency of

various agricultural research and extension education strategies which have been tried in the developing countries." (p. 1)

The first section presents an assessment of the impact of national and international social, economic, political, and technological factors on the evolution of agricultural research and educational institutions in third world countries. It begins with a chapter that reviews the historical context of the evolution of the U.S. land grant system, focusing on the importance that mass political participation and a secure funding base had on creating a responsive land grant system, the relative absence of these conditions in third world countries, and the impact that U.S. development assistance efforts have had on parallel institutions in the third world. Forty years of technical assistance and development efforts in Peru are reviewed in the second chapter. The relative failure of these efforts is attributed to the lack of nontechnological conditions necessary for development to occur.

Part two of the book focuses on nontechnical challenges to agricultural development. It includes a chapter on conventional methods of communication of agricultural technologies, focusing on extension systems and scientists. This is followed by a discussion of women in agricultural development, factors related to these programs, and their lack of progress. The last three chapters of this section deal with conventional extension systems, such as the American system, and the need for agricultural scientists and educators to give greater attention to indigenous agricultural systems in order to address better the needs of small farmers.

The last section includes an analysis of international agricultural research centers and farming systems research and extension models as potential guides for advancing agricultural development in the third world. Vern Ruttan summarizes the evolution of international research during the past four decades, focusing on organizational and management issues. He also questions the ability of U.S. universities to contribute effectively to applied research in the tropics. The development and use of farming systems is described in the final chapter. The discussion focuses on the importance of involving small-scale farm producers and their families in research and development aimed at generating appropriate technology.

The book is a contribution to the development literature, particularly that which deals with agricultural institution building in the third world. Most of the ideas found in it are not new, having been presented and discussed elsewhere by the contributing authors and others. However, nowhere have they all been summarized within the context of the U.S. land grant system, its core activities, and its contributions to agricultural development in other countries. This alone makes it a useful addition to personal and institutional library collections.

Development administrators and students of third world agricultural development will benefit from reading the book. Compton competently summarizes the contents of each section, identifies and expanc on the major themes of individual chapters, and higl lights points of intersection among them. His insigh guide the reader through individual sections and serv as useful tools for review.

I found the book to be an excellent summary c past and present contributions of the land grant sy tem to international development efforts, particularl those supported by bilateral and multilateral donor It illustrates the obvious limitations of the U.S. lan grant model to promote agricultural development i the third world. Its major shortcoming is the lack c a concise and critical discussion of what the U.S model really has to offer to these countries. But, ther Compton may have decided to let the reader decid this.

Fuller, Wayne A. ***Measurement Error Models.*** **Ne York: John Wiley & Sons, 1987, xxiii + 44 pp., $44.95.**

A measurement error is made when the observe variable differs from the true variable. For exampl suppose one wants to predict corn yield as a functio of available soil nitrogen. One must sample the so of the experimental plot and do a laboratory analysi of the sample. The resulting observation on soil ni trogen will be only an estimate of the unknown tru value. Use of standard statistical techniques can yiel significantly biased and inconsistent estimates of th parameters of a model when measurement error i present. *Measurement Error Models* was written i order to increase the use of statistical techniques ex plicitly recognizing the presence of measurement er ror. The author suggests the book may be used as text for a graduate course concentrating on statistic analysis in the presence of measurement error or a an auxiliary text in courses on statistical methodo ogy. The book should serve these purposes well, bu it will be even more useful as a reference for re searchers.

Psychologists and sociologists have long recog nized that their data included measurement or re sponse error, perhaps because their data were so di rectly collected from human subjects. Tradition economic variables, such as age, income, educatior and unemployment or poverty status, can also b strongly affected by response bias. Fuller shows th 50% of the mean square error can arise from respons bias in reasonable sample sizes.

Least squares estimates of parameters in model that contain variables measured with error are biase and inconsistent because the equation's error term i no longer independent of a regressor. Judge et al. also in the Wiley series in probability and mathe matical statistics, present an excellent overview c estimation procedures for models containing errors i variables (p. 510), but Fuller expands considerabl

on the subject, giving computational formulas, numerical examples, crucial theorems, and their proofs.

Chapter 1 introduces the problems of measurement error when there is a single explanatory variable. Careful distinction is made between models in which the independent variable is fixed and models in which the independent variable is random. The reliability ratio is explained using examples from genetics. Knowing the reliability ratio, one can construct an unbiased estimate of the beta parameter and perform the usual hypothesis testing.

In general, the properties of the estimators corrected for the measurement error depend on the type of information that is available to identify the model. Some additional information, such as the reliability ratio or the variance of the measurement error, must be available or an equation with errors in the variables cannot be identified. Fuller gives the appropriate formulas to calculate parameters, significance tests, and confidence intervals, correcting for measurement error. He supports most of the formulas with excellent numerical examples. The chapter concludes with brief sections describing what to do when x is not normally distributed, how to use Wald's grouping technique, and the importance of measurement error if the objective is prediction.

The second chapter extends the results of the first chapter to models with more than one independent variable. The calculations become more formidable in this section, and Fuller recommends appropriate statistical software. One section is devoted to the small-sample properties of estimators and to modifications one can make to improve small-sample behavior.

Chapter 3 relates the classical regression assumptions, specifying appropriate formulas when errors are heterogenous or non-normally distributed, and for models with multinomial random variables. The latter occurs when the observation process consists of assigning each member of a sample to one of r categories. An example is the reporting of employment status.

The final chapter extends the treatment of measurement error models to the case where true variables satisfy more than one linear equation. It concludes by expanding the simple factor model of chapter 1, where elements of an observation vector were linear functions of a single unobserved factor, to higher dimensions.

Each chapter contains exercises and references. There are helpful lists of examples and of principal results at the beginning of the book, features more textbooks ought to contain.

I have only a few minor complaints. First, a two-page appendix on notation follows the first chapter; it should precede it. Second, the first ANOVA table appears (p. 135) with insufficient information; a reader unfamiliar with ANOVA cannot understand it. This flaw stands out because the author is generally so extremely careful to assume no more than standard regression knowledge in his readers. Third, many of the calculations are performed using the SUPER CARP program. It would be nice to see a few sample programs.

This book condenses and synthesizes fifty years of measurement research. It is an authoritative summary because much of the research in the last fifteen years was done by Fuller. It is an immense help to someone who needs to use a measurement error model. Without this book one would have to master an extremely large and scattered set of published articles, each with a different notation and—if from the psychology literature—written in an alien tongue.

Greeley, Martin. *Postharvest Losses, Technology, and Employment—The Case of Rice in Bangladash*. Boulder CO: Westview Press, 1987, xvii + 345 pp., $35.00.

This is a scholarly and penetrating book. It effectively rewrites a chapter in the annals of development thinking. At the same time, it puts out in the cold one of the more profitable "milking cows" of the development game.

Throughout the 1970s a whole industry grew up around postharvest losses in developing countries. These were allegedly both excessive, typically estimated at 10%–15% at least (which, anyway, is about the amount that goes over the back of an average combine harvester), and remediable, by the application of Western technology and development assistance. Professional reputations were built, the programs of whole institutes were justified, high-level committees were indulged, hundreds of millions of dollars were invested by development agencies, and considerable profits were made, all in the effort to combat this egregious shortcoming in the competence of peasants.

This book presents a Bangladesh case study of the farm-level postharvest system, based on meticulous fact gathering over three years. Using the measurements obtained, together with supporting information from other sources, the author tests, and rejects, the conventional assumptions that farm-level postharvest losses are large, that they can be prevented cost effectively by technical change, and that as a consequence there will be more food consumption by hungry people.

Having demonstrated rather convincingly that none of these assumptions is true, and why, the author goes on to examine farm-level technical change in postharvest practices in Bangladesh. He concludes that these changes are reducing food availability, reduc-

ing the number of work places, and are damaging to the welfare of some of the poorest rural households. Further analysis is used to explain farmer adoption of these technical changes in terms of cost savings, to explore social costs and benefits that they give rise to, and to suggest the types of intervention that might be appropriate.

Chapter 1 of the book is introductory. Chapter 2, entitled "The Postharvest System and World Hunger: The Debate on Neglect and the Neglects of the Debate" examines the conceptions and misconceptions concerning the role of postharvest food loss in the fight against hunger. It is argued that the advocates of loss prevention programs were aware of the unreliability of available loss estimates but nevertheless used them, often selectively, to support their case.

Chapter 3 describes "Rice in Bangladesh: The Farm-Level Postharvest System" in careful detail. It provides working definitions of postharvest and food losses, and emphasizes "measurability, sound definition and economic valuation" of quantitative loss assessments. It includes, *inter alia,* a comprehensive account of rice culture in Bangladesh.

The main evidence on food losses is presented in chapter 4, "Bangladesh Farm-Level Food Losses: The Evidence Against the High Loss Lobby," most of which is devoted to a discussion of the loss assessment methods employed in the study. The losses measured provide detailed evidence that farmers are efficient in avoiding postharvest losses, and that what does occur (mainly in storage) is unavoidable in terms of cost-effective farm-level loss prevention interventions.

Chapter 5, "Technical Change: Pedal Threshing," shows that despite the fact that pedal threshers cause higher food losses, they are still a profitable investment for machine owners and renters because of the substantial reduction in labor hours per ton. But the interesting feature is that the labor saved is all family labor, which is attributed to family labor constraints, machine-owner monopoly control of labor used, and growing farm management requirements of family labor. This latter point is discussed persuasively, and at some length, but without a definite conclusion.

Chapter 6, "Technical Change: "Rice Milling," examines the replacement of manual rice husking by the huller rice mill, with some one-third of on-farm rice consumption being mill-processed in the mid-1980s. The author notes no differences in food availability with the new technology because milling losses are recovered in subsequent cleaning and sorting practices. The female wage labor loss is judged more serious. Cost-benefit analysis shows the rice huller to be more profitable than manual husking at market and efficiency prices, but once social weights are introduced the manual method is very much more profitable.

The final, chapter 7, "Policy Implications: Programmes for Rural Women," builds on the results of chapter 6 and departs from the main theme of postharvest food loss. It argues for special programs for rural women, to substitute for the employment lc through technical changes, as the likely more effe tive policy response in the face of current trends. Tl universality of the female labor displacement patte is emphasized. The potential of development pr grams for wage labor women to address both gend issues and poverty issues concurrently and effective is strongly argued. These arguments are supported l field evidence.

One cannot but be impressed by the rigor, tran parency, and relevance of the work this book co veys. The study is a model of applied empirical ana ysis that many students might well emulate. The bo itself is well written, readable, and devastating. Tl author deserves the highest accolades of our profe sion.

The book is strongly recommended as an antidc for anyone inclined to organize another task-forc workshop, or international conference on postharve losses—and less costly too!

Graham Donaldson
World Bank

Lofchie, Michael F. ***The Policy Factor: Agricu tural Performance in Kenya and Tanzani*** **Boulder CO: Lynne Rienner Publishers, 198 xi + 235 pp., price unknown.**

This is an interesting and useful book. It provides readable account of the external and internal facto that seem to explain the serious food and agricultu problems that have emerged in sub-Saharan Afri during the past two decades. The emphasis on co paring "the economic performance of an agricultu ally successful country, Kenya, with that of an a ricultural failure, Tanzania" is appropriate and mak it possible to go beyond a journalistic account of t African food problem and associated causal facto

An especially valuable contribution of the book in making available U.S. Department of Agricultu time-series data, typically annual estimates for t 1966–86 period, comparing production and yield e timates for major export, industrial, and food crop Those tables and accompanying diagrams, which ma it easy to compare the performance of the two cou tries, confirm Lofchie's summary conclusion abc success and failure. He recognizes that these es mates are subject to a considerable margin of errc with food production statistics for Tanzania bei expecially unreliable. The performance contrasts a most striking, however, for export crops for whi supporting evidence from trade statistics is availabl (Even the export statistics are subject to qualific tion, because of illicit exports from Tanzania and b cause Kenya's export figures may include some cc fee or other produce smuggled into the country fro Uganda or Tanzania.)

Although Lofchie acknowledges that external fa tors, notably the Uganda War and the sharp increas in petroleum prices in 1973 and 1979, contributed

Tanzania's economic decline, his emphasis is on the effects of internal policies and the interacting effects of declining exports, balance of payments deficits (aggravated by increased food imports as well as the rise in oil prices), inflation, extremely low rates of utilization of the country's industrial capacity, and a severe debt crisis. Major attention is given to four policies that had "ruinous impact on the country's once-thriving agricultural system: (1) overvaluation of the currency; (2) suppression of agricultural producer prices; (3) implementation of agricultural policy through a system of monopolistic parastatal corporations; and (4) pursuit of an industrial strategy based on the principle of import substitution" (p. 119). Again, the book provides a convenient source for data that the USDA has compiled on official prices for major commodities in each country, plus price series adjusted for overvaluation on the basis of parallel market exchange rates together with price ratios for the two countries based on those adjusted prices. Unfortunately, the series for coffee and tea extend only to 1979/80; the figures for corn and several other food crops extend to 1986.

The book is in general the well-informed account that one would expect of an author who is director of UCLA's prestigious African Studies Program. There is one surprising error in giving Tanzania's date of independence as 1966 instead of 1961 (p. 70). There is also a tendency for the author to be unrelenting in his criticism of Tanzania's policy makers, whereas he sometimes seems to lean over backward to offer a favorable interpretation of decisions by Kenya's policy makers.

As an economist, my principal criticism of the book is its failure to distinguish clearly between activities, for example the provision of public goods such as agricultural research, for which public sector intervention is likely to be critically important, and other types of activities for which competing private firms (and independent coops) have a comparative advantage. Lofchie notes that Kenya's Tea Development Authority (KTDA) was "an exemplar in fostering smallholder development" (p. 166). But he fails to point out that the KTDA was a significant institutional innovation because it enabled smallholders to produce high-quality tea for export by carrying out those activities—especially prompt collection and processing of tea leaves—for which economies of scale are important. Prior to that innovation tea had been regarded as a "plantation crop" par excellence.

It also should be mentioned that Lofchie, a political scientist, makes a surprisingly limited contribution to explaining why Kenya's policy makers opted for an appropriate agricultural strategy whereas policy makers in Tanzania pursued policies that had disastrous consequences. He relies mainly on an "urban bias-weak state paradigm" that is based on Michael Lipton's *Why Poor People Stay Poor* and Robert Bates' *Markets and States in Tropical Africa*. The fact that the book had a long gestation period probably accounts for the fact that he does not draw on a fairly recent book by Richard Sandbrook (1985) which, in this reviewer's opinion, adds considerably to the insights that can be derived from Lipton and Bates.

Sandbrook, Richard, with Judith Barker. *The Politics of Africa's Economic Stagnation*. Cambridge: Cambridge University Press, 1985.

Luttrell, Clifton B. *The High Cost of Farm Welfare*. Washington DC: The CATO Institute, 1989, xi + 149 pp., $19.95 hardback, $9.95 paper.

The combination of this book's title and its publisher should be sufficient to alert the reader that an attack on government involvement in agriculture is forthcoming. Of course, there is nothing wrong with that and the criticism may be well deserved. Luttrell, an agricultural economist with the St. Louis Federal Reserve Bank for more than thirty-five years, has offered a short (i.e., 130 pages of text and tables), highly-readable summary of the history and economics of government agricultural programs in the United States. Given the length of the book and its broad scope, some of the analysis is necessarily superficial—indeed, in some cases too oversimplified, e.g., "the increasing liberality of FmHA lending on farmland in the 1970s led to spiraling land values" (p. 78)—but much of the analysis is difficult to argue with, at least for market-oriented economists.

Luttrell traces the history of federal government agricultural programs from initial limited involvement in such areas as farmer education and support for farm cooperatives through the development and rapid expansion of price support and supply control actions in the 1930s to the "alphabet soup" of payment-in-kind (PIK) and dairy buyout (DTP) programs of the 1980s. Among the eleven chapters are those on the New Deal farm programs, supply management, surplus problems and export subsidies, food stamps, farm credit, the dairy and sugar programs, and farm poverty. Most of this will not be new to any professional economist, but it offers a good summary of the various programs.

Essentially, Luttrell's position is conventional. He argues that many of the support programs increased returns to farmers in the short run (although at very high cost) but generally provided incentives to increase production. Combined with the capitalization of the subsidies into land values (with all that implies for higher land costs), this tended to drive average returns to normal in the long run. The net effect has been to attract or maintain excess resources in agriculture. Thus, it is argued that these programs failed in their primary objective and have done so at substantial deadweight cost. Luttrell argues that this failure to increase farm income then provided the basis

(i.e., "low" farm income) for another round of even higher-cost programs.

> The simultaneous existence of large government expenditure on farm programs in the mid-1980s with relatively small impact on net farm income (realized government losses in some years exceeded net farm income and USDA expenditures were two or three times net farm income) confirms this principle of ineffectual subsidy ratcheting. (p. 121)

Published estimates of the annual deadweight loss of federal subsidy programs [ranging from $1.5 billion to the $5.2 billion (Council of Economic Advisors)] are criticized because of their focus on short-run effects only. Using some "quick and dirty" economics that include long-run effects, Luttrell concludes that the annual deadweight loss is more than $30 billion. While one can quibble about the magnitude, there is little question that the loss is substantial.

The book also summarizes some of the evidence indicating that many of the agricultural subisdy programs violate the conventional notion of vertical equity. That is, the income transfers are from lower to higher income individuals. If the farm problem is really one of poverty, Luttrell argues that $2 billion per year in direct income transfers to farmers whose net farm income falls below the official poverty line would eliminate the farm poverty deficit which currently is at least partially if not completely offset by off-farm income. Alternatively, if the objective is somehow to maintain an agrarian society as it exists today, he suggests that all farm programs be dismantled over a five-year period and the adverse short-term income impacts mitigated by making annual payments to farmers of 50% of their annual average net farm income for the past three years. These payments would be made until the farmer reached age seventy, with appropriate adjustments for inflation. The 1987 cost of this program, about $15 billion, is about half of Luttrell's estimate of the social cost of the existing arrangement and has the advantage of declining each year as some farmers reach age seventy and phase out of the program. In forty or fifty years the cost of this program would reach zero as all existing farmers attained the "retirement" age.

This book is certainly timely. While it is possible that the economic structure and conditions facing agriculture at the depth of the depression justified some sort of significant government support program, the situation in 1990 is far different. The programs we have now may have been suited to an era of fifty years ago, but Luttrell makes a strong case that they are not appropriate to today's agriculture. Of course, some already have spoken plainly about the need to reorient the system. (For example, see the interchange between Tweeten and Knutson.) The pressure to reduce federal government spending, the continuing shift of political power away from rural areas, and a public awareness that many of these programs are socially inefficient probably will continue to threaten agricultural subsidy and control programs.

This book has not been written for the mainstream agricultural economist (although many will enjoy reading it), but it may very well find a niche on the reading list of the typical agricultural policy course. Although not a balanced treatment of the problem, it provides a good bit of history, it is definitely thought provoking, and even a slow reader can get through it in a couple of hours. Some, perhaps many, may disagree with the Luttrell position; but, clearly, he speaks for a growing number of people both inside and out of the agriculture establishment.

Mitchell, Robert Cameron, and Richard T. Carson. *Using Surveys to Value Public Goods: The Contingent Valuation Method.* Washington DC: Resources for the Future, 1989, xix + 463 pp., price unknown.

In his forward, Raymond Kopp (p. xv) explains that this book "provides decision makers, policy analysts, and social scientists with a detailed discussion of a new technique for the valuation of goods not traded in private markets. Termed contingent valuation, the technique draws upon economic theory and the methods of survey research to elicit directly from consumers the values they place upon public goods."

Mitchell and Carson's blend of economics and survey methodology, together with liberal doses of sociology, should make their book a welcome addition to the literature on contingent valuation (CV). Specialists in that technique may quibble about numerous points. Nevertheless, this is the best book available on the topic.

The first five chapters introduce CV. Some of the topics covered include the welfare theory underlying valuation, valuation under uncertainty, the advantages of CV compared to other techniques, alternative CV question formats, the theoretical merits and practical usefulness of referenda questions for valuing public goods, existence value, and possible theoretical relationships between willingness to pay and compensation demanded.

A particularly noteworthy contribution of the early chapters is an exposition of the dual concepts of reliability and validity as they apply to CV. Many have voiced skepticism about the accuracy of the technique. Feeling the need to address these concerns in

a more systematic way, early CV researchers conceived of a number of potential "biases" that could have been present in their studies. One paper on the topic (Schulze, d'Arge, and Brookshire), for example, spoke of strategic, hypothetical, information, and other biases. This was an important step in the history of CV because it assigned names to the concerns of the skeptics and thus set the stage for empirically addressing those concerns. However, the term "bias" was not clearly defined, and the boundaries between the various "biases" were not always apparent. The concepts of reliability and validity have served well in addressing measurement problems elsewhere and, as developed by Mitchell and Carson, represent a promising avenue for systematically and rigorously investigating the accuracy of CV.

Chapters 6 through 9 survey evidence related to the reliability and validity of CV. Concerns about the willingness of people to respond accurately to CV questions stem directly from Samuelson's argument that people have an incentive to behave strategically, rather than telling the truth about their values for public goods. Based on a detailed review of the public goods literature, the authors conclude: "The evidence for willingness to pay . . . suggests that strategic bias is not a significant problem for CV studies under *most* conditions. Instead of being a fundamental, unavoidable threat to the CV method, strategic behavior is just one of many possible sources of bias which the designer of a CV study must take into account" (p. 170).

The ability of study subjects to give meaningful responses to CV questions is the next topic addressed. Concerns here have focused on the ability of respondents to predict in surveys how they would behave in a market setting or a voting booth were they confronted with real opportunities to affect the availability of recreational, environmental, or other commodities or services and the amount they would actually pay. For decades, social psychologists have been investigating whether "behavioral intentions" and other attitudes, as expressed through surveys and other media, can be used to predict behavior. The conclusion to be drawn from Mitchell and Carson's survey of the attitude-behavior literature is somewhat optimistic: The CV researcher is investigating a form of behavioral intention that could be a fairly accurate predictor of behavior, but pitfalls exist that must be guarded against through careful survey design. Quoting them (p. 188) directly, "The key problem facing the designer of a CV study . . . is the novelty of valuing a public good, given the respondents' varying degrees of familiarity with the good being valued and how they currently pay for its provision."

In chapter 9, Mitchell and Carson examine experimental studies on the validity of CV, concluding that the results generally support its accuracy when it is used to measure willingness to pay. In the process, they further develop the concept of validity in a way that future researchers will find very useful.

Chapters 10 through 12 provide explicit advice for designing CV studies. Chapter 10 reviews some ways to enhance reliability, including ways to deal with the thorny problem of outliers. Chapter 11 categorizes ways in which systematic errors might threaten the validity of contingent valuation results. Mitchell and Carson significantly improve upon previous work by predicating their discussion on assumptions about human behavior that are more realistic than the assumptions underlying *homo economicus* and by making positive suggestions, based on general experience in survey research, for avoiding problems. Chapter 12 provides sound advice on sampling and aggregation issues.

Chapter 13 presents the conclusions of the book. Its centerpiece is a list of criteria for evaluating CV studies, which is more thoughtfully conceived and empirically grounded than the "reference operating conditions" offered by Cummings, Brookshire, and Schulze (p. 104).

The usefulness of this book extends to its appendices, which summarize the content, form, and other details of more than 100 CV surveys, present one of Mitchell and Carson's own surveys as an illustration, and discuss statistical aspects of hypothesis testing and experimental design. The bibliography is composed of fifty-three pages of useful references.

Researchers whose work is cited in this book may find a few "flies in the ointment." I certainly did in their treatment of some of my own work. Regardless, Mitchell and Carson have succeeded in their "attempt to contribute to an understanding of what constitutes best practice in contingent valuation surveys" (p. 299). Their book should serve as a valuable research reference and teaching tool for many years to come.

Molnar, J. J., and H. Kinnucan, eds. *Biotechnology and the New Agricultural Revolution.* Boulder CO: Westview Press, AAAS Selected Symposium 108, 1989, 288 pp., price unknown.

This volume is the edited proceedings from a 1986 symposium at the annual meeting of the American Association for the Advancement of Science. The

preface (p. xiii) notes, "The papers are intended to provide some understanding of the ways biotechnology is reshaping agriculture—research, regulation, and production—and the major directions that can be anticipated." The volume itself is organized in a slightly different fashion with the three parts titled "Institutional Issues," "Shifts in Farming and Agriculture," and "International Perspectives." These headings encompass a total of ten papers plus an introduction and conclusion by the editors. The work is well indexed and contains an impressive list of references.

Life, experience and research tell us, tends to move in cycles, and so it has been with attitudes toward biotechnology. From incredulity following the first announcements of gene splicing, the public and business went through a period of euphoria, when biotechnology was seen as solving all problems. Doubts emerged as the technology advanced more slowly than suggested. Environmental concerns also surfaced as a largely new class of products were poised for full release. Subsequently the public seems to have moved to a more balanced wait-and-see attitude to the technologies and their likely impacts, both positive and negative.

The bulk of papers in this volume fit solidly in the period of rising doubts about biotechnology. The tone is set by the twelve-page introduction, of which one describes in general terms the potential benefits of biotechnology while eleven raise concerns. The concerns addressed fall into three major categories: input supply concentration, safety and regulation, and farm structure. The treatment can be described as being predominantly sociological. That is true even though the contributing authors and papers are split evenly between sociologists and economists (two additional papers are more production based). However, one of the economics papers is, for an audience of agricultural economists, a general overview of the adoption literature, while another—an examination of the competitiveness of U.S. agriculture as revealed by patent records—is a substantial effort but has little to do with biotechnology. The number of biotechnology patents at the time of writing was simply too few to draw any real conclusions. Thus, the overall impact of the volume is more one of social analysis than economic.

For economists, it is often beneficial to be exposed to different interpretations of the implications of technological change. Nonetheless, I find much of the treatment here incomplete. For example, the Kenney paper takes a largely conspiratorial view of regulation: "In fact, most public representatives and legal counsel warned industry that the public required the 'perception' of regulation and that real regulation was not necessary" (p. 92). Undoubtedly that is an aspect of the regulatory environment, but by no means all of it. Indeed, a case can be made that some aspects of biotechnology are too effectively regulated. In their discussion of the impacts of biotechnology on the division of research between industry and universities, Lacy and Busch claim: "The division of labor has been until the present, fairly clear" (p. 31). In my experience, the relationship between agribusiness and universities has never been really clear. The feeling of incompleteness is enhanced by the two production-based papers. Brady, writing on biotechnology applications to developing-country agriculture, really gives a litany of USAID projects. And Terrill's contribution on biotechnology in livestock production is perplexing in its focus on small ruminants. "The potential to increase efficiency of small ruminant meat animals through biotechnology selection research is so great that it will be difficult for any other technology to have a practical impact on farm production" (p. 112). That statement overlooks much exciting work which had been done on small mammals and is potentially extendable to the major red meat species.

Part of what is happening is the rapid advances made since these papers were written. They have become somewhat dated despite obvious efforts to extend the references. As examples, there is a reference to the delayed field testing of ice-minus bacteria, which has subsequently been tested (with no apparent problems) in the environment. Buttel and Geisler (p. 145) raise questions about the adoption predictions of bST given some evidence of lower responses in the South. Subsequent research has shown equivalent milk production response when common heat stress-reducing practices are followed (Bauman, personal communication). It should be noted that three of the papers focus on bST which then, as now, is one of a very few biotech products that is likely to have a major impact on agriculture in the near term.

But these are minor points. More substantively, one can consider the paper by Geisler and DuPuis, which notes the policy and attitude changes in extension and other programs needed "if the adoption of bST is not to be a self-fulfilling prophecy in terms of distributional effects . . ." (p. 229). They proceed to describe programs directed to "exit prevention," the avoidance of prejudging farmers as progressive or not, and the use of multitiered price supports. Many of these points are well taken, and some states—certainly here in New York—are already working to enhance the potential for successful adoption of bST among their dairy farmers. But at the extreme, these writers are proposing a fundamental change in the operations of the U.S. agricultural sector away from market forces and toward more managed structural change. Such a step may indeed be appropriate, but the problems and limitations require far more attention than they receive here. Geisler and DuPuis, for example, describe the merits of Japanese land tenure and extension systems in promoting a "unimodel farm-size distribution" and "relatively efficient small family farms" (p. 236). No mention is made of the horrendous subsidy cost of that system.

Proceedings papers by their nature tend to be disparate. It is the challenge to the organizers/editors to coordinate the papers as a whole prior to presen-

tation or to interrelate them in the conclusions to the published proceedings. Molnar and Kinnucan, while noting that "biotechnology is only one of many sources of change in agriculture . . ." (p. 254), do not provide a volume which integrates biotechnology into the dynamics of the agricultural sector. The sum does not exceed the total of its varied parts.

William Lesser
Cornell University

Morales, Edmundo, *Cocaine—White Gold Rush in Peru*. Tucson: University of Arizona Press, 1989, 228 pp., price unknown.

Morales, a Peruvian with a doctorate in sociology from the City University of New York, is an acknowledged expert on cocaine production and trafficking. He employed an ethnographic research method in developing the data base for his book. He interviewed more than 100 families in a town near his birthplace in the Andes of Peru, more than 70 coca paste workers, and another 150 persons connected with the cocaine economy.

Morales questions what economic force will replace coca. The purpose of the book is to suggest alternative means of making a living for impoverished populations currently supporting the cocaine black market.

Prior to addressing the major purpose, he offers three chapters on traditional uses of coca leaves, the physical setting and demographics of coca agriculture, coca culture, and the cocaine economy.

The chewing of coca leaves, beginning perhaps about 1800 B.C., is associated with work situations, rituals, and religious practices. For centuries landlords, mine owners, and other employers have served coca leaves to their workers as a measure of social control. The chewing of coca increased the vigor and morale of workers. Coca chewing is believed to raise individual spirits, ward off hunger, reduce fatigue, and, by many, to resolve health problems.

The second chapter reviews important information relating to the severe economic conditions of the Andean region of Peru. The unsuccessful land reform of 1969 raised expectations but had little impact on real incomes. Even large outmigration, to Lima and other coastal cities, has not altered the level of economic opportunities. More migration to the high jungles of Peru involved large numbers and extensive participation in the illegal coca economy, annually adding $2 billion in Peru and $80 billion worldwide. Agriculture developmental alternatives (coca substitutes) in the high jungle (tea, coffee, cacao, rice, corn, etc.) have been limited due to the lack of infrastructure, markets, technology and its transfer, price controls, and poor environmental conditions.

The next chapter describes the production of coca plants. Harvests are made five times a year beginning one year after transplanting and continue for twenty-five–thirty years. The high quality Peruvian coca plants require no fertilizer, very low maintenance inputs, and perform well on poor soils, steep hillsides, and high elevations with heavy or light rains.

Recently, Peru has annually produced 100,000 hectares of coca yielding 160,000 metric tons of dried leaves. Some 5,500 metric tons are consumed by coca-chewing Andean Indians and peasants, leaving 96% to the illicit economy.

Coca leaves are treated to extract alkaloids by producing coca paste. The coca paste transformation requires four chemical agents, sulfuric acid and sodium carbonate, that move within Peru through the underground economy. The other two are calcium oxide (unslaked lime) and kerosene, readily available throughout the high jungles. This cottage industry has modest capital requirements but is dependent upon a good chemist or an experienced mixer. The underground coca paste economy is well organized and includes an outside boss, international linkmen, a local boss, his bodyguards, and collectors of coca paste along with a transport/security support staff.

Through an elaborate trafficking system, the coca paste reaches laboratories for conversion to cocaine hydrochloride. This process requires a capable chemist working with hydrochloric acid, acetone, and ether.

Annually, the 160,000 metric tons of coca leaves in Peru can produce 1,500 metric tons of coca paste. This paste converts to about 400 metric tons of uncut cocaine hydrochloride. A kilo (2.2 pounds) of cocaine may cost some $5,000 to produce and transport, has a New York wholesale price of $35,000 (50% purity) and can yield retail sales of adulterated cocaine of $200,000.

Morales characterizes the Peruvian underground cocaine economy as a cosmetic modernization of the countryside. The industry is subject to, and completely dependent upon, internationally organized crime. The White Gold Rush does not support a sound, healthy, and independent national economy. There are increasing problems of urban and rural addiction along with growing levels of official corruption.

Prior to addressing his major purpose, alternatives for impoverished people, the author attacks the myth of the alliance of two undergrounds. The cocaine underground is a social organization with pure economic interests, while the terrorist underground is a fanatic political ideology structured to resolve social injustices. The alliance is unreal in that the illicit economy cannot afford to support political movements that do not lead to accumulated wealth.

Turning to U.S. efforts in Peru to reduce coca leaf supply, the author argues the U.S. policy is, and will continue to be, ineffective. U.S. efforts to eradicate and interdict supply and to support crop substitution and plant destruction are incorrect policies.

The author argues that a more rational use of the billions now used in unsuccessful programs would be a rational and authentic economic development program in the coca leaf area. Large investments in infrastructure, markets, rational policies, technology generation and transfer, education and health would be required.

Other suggestions for U.S. collaborative actions,

not his own, focus on stricter law enforcement on producers and gateway nations along with consideration of a program to purchase and destroy coca leaves. Another direct U.S. action should focus on enhanced educational programs to reduce the demand for cocaine.

The book is well written and should be of interest to people impacted by the coca industry and concerned over alternative U.S. actions.

Rasmussen, Wayne D. *Taking the University to the People: Seventy-Five Years of Cooperative Extension*. Ames: Iowa State University Press, 1989, x + 300 pp., $24.95.

This book was commissioned by the Extension Committee on Organization and Policy (ECOP) to commemorate the seventy-fifth anniversary of the Cooperative Extension Service. Its purpose is described by the members of the Seventy-Fifth Anniversary Book Task Force in the foreword: "A history of the evolution of Extension is of some importance at this point in its life cycle. But, more important, a modern text detailing the unique characteristics, evolution of methodologies, and current institutional changes under way in the Cooperative Extension System is the more pertinent document" (p. xviii). Funding for this project was provided by Extension's supporting organizations, including partners in the Extension system who guaranteed advance orders in excess of ten thousand copies.

Given the nature of the charge and the sources of funding, it should come as no surprise that *Taking the University to the People* is not an objective evaluation of the strengths and weaknesses of Extension. Rather, it focuses overwhelmingly on Extension's strengths and successes. Any evaluation is mostly a rehash of the ECOP Futures Task Force Report; therefore, evaluations of that ECOP report by Henderson and Wallace are also applicable to this book. In spite of its lack of objectivity. *Taking the University to the People* is a carefully researched and scholarly work about the history of Extension.

Following brief references to the Morrill Land Grant and Smith-Lever Acts, chapter 1 provides a brief overview of Extension as it exists today. Rasmussen carefully walks the reader through the federal, state, and county partnership and its linkages to the USDA and land grant universities. He also outlines Extension financing, staffing, and supporting organizations. The introductory chapter concludes with descriptions of Extension's researched-based educational programs in the United States and imitated, but less effective, programs around the world.

Chapters 2 and 3 trace Extension's roots from George Washington's support for agriculture in 1796 through the passage of the Smith-Lever Act in 1914. Rasmussen carefully documents the evolution of Extension out of organizations and activities, such as agricultural societies and clubs, farm journals, the Morrill and Hatch Acts, boys' and girls' clubs, and later, the Progressive movement and the Country Life Commission.

Chapters 4 and 5 describe the establishment of Extension and its responses to two world wars and the Depression. Rasmussen skillfully documents the origins of Extension's orientation to three principal groups—agriculture, homemakers, and youth. He also explains its liaisons to other institutions and agencies such as the American Farm Bureau, the Agricultural Adjustment Administration, Soil Conservation Service, the Farm Credit System, the Rural Electrification Administration, and the Tennessee Valley Authority. Extension's dual roles as an educational institution and action agency are portrayed in the development of educational methodology and programs such as the Women's Land Army and Victory Farm Volunteers.

Chapters 6 through 9 contain extensive anecdotal examples of Extension's past and present programs in agriculture, home economics, 4-H, and rural and community development. While informative, these chapters suffer from the author's apparent use of Extension's own success-story reporting system, which emphasizes numbers reached, behavioral changes, and results. We learn, for example, that "in 1985 the urban gardening program was active in twenty-one cities. In addition to the federal appropriation of $3.5 million, local governments and private agencies contributed another $1 million. A staff of 171 conducted the program, with help from 2,300 volunteers. Some 186,000 participants worked an area equivalent to more than 670 acres, from which about $20 million in produce was harvested" (p. 136). By my calculations, that amounts to nearly $30,000 per acre, slightly more than $100 per person and over $4 per dollar invested!

Chapter 10, "Beginning the Next Seventy-Five Years," is even more disappointing. Those who have read the ECOP Futures Task Force Report and the outcome of ECOP's National Priority Initiative Process, "Cooperative Extension System National Initiatives: Focus on Issues" can skip the last chapter.

The book concludes with five appendices containing biosketches all of Extension Service administrators, a list of Distinguished Service Ruby Awards, a breakdown of funding from 1914 to 1988, the Smith-Lever Act of 1914 as amended through 1985, and the Memoranda of Understanding and Project Agreements between the Land-Grant Institutions and the USDA in effect in 1988. The book also contains nearly sixty photographs and illustrations.

Taking the University to the People is a fascinating and informative historical account of the Cooperative Extension Service. It should be required reading for all new Extension employees and recommended reading for all present and past employees; however, those looking for an objective analysis of the past or a blueprint for the future will be disappointed.

Sperling, Daniel. *New Transportation Fuels: A Strategic Approach to Technological Change*. Berkeley: University of California Press, 1988, x + 532 pp., $45.

The U.S. transportation sector relies almost entirely on petroleum products and accounts for 63% of the nation's petroleum use. The U.S. Department of Energy forecasts that foreign supply will constitute 55% of total U.S. petroleum consumption by year 2000, with much of it coming from the unstable Middle East area. Thus, this sector is particularly vulnerable to supply interruptions. There also is concern that, in some twenty to forty years, we will have depleted most of the world's easily accessible high-quality petroleum. Developing new oil fields will become increasingly expensive.

Environmental concerns also are prompting efforts to find new transportation fuels that will reduce ozone, carbon dioxide, and nitrous oxide and other pollution. Most books that address alternative energy options disregard the changes necessary for the candidate fuels to become available. As a result, some options advocated are utopian and virtually impossible to achieve in a democratic society.

Sperling takes a more practical approach by developing a pathway concept of analysis that focuses on "how to generate the conditions that create and nurture" new energy sources (p. 28). He thoroughly explores the impacts and implications of technological choices. Sperling verifies that there is a transportation fuel problem.

In a section titled "Getting There From Here," Sperling identifies the barriers that restrict adoption and outlines strategies for adoption of several candidate fuels. This section is must reading for policy analysts. The final major section, "Making Choices," may startle many economists. In chapter 19, Sperling states: "The objective of this chapter is to convince the reader that conventional economic analysis and passive reliance on the market system *will not and should not* by themselves determine long-term transportation energy choices" (p. 395). Many policy makers wish to believe that a free market exists and that new products have unlimited entry to the marketplace. They choose to ignore government initiatives that tilt the playing field and distort the market. Sperling cites a number of such examples, including the Brazilian government's subsidization of its ethanol industry through credit tools, sugarcane planting, construction of conversion facilities, redesigning of motor vehicles, retooling of motor vehicle manufacturing plants, price manipulation of ethanol and gasoline, and changes in oil refining and fuel distribution. In the United States, he cites various public actions that interfere with market-oriented pricing. For example, agricultural market distortions resulting from federal commodity programs to maintain grain prices substantially higher than they otherwise would be are detrimental to the U.S. fuel ethanol industry which depends on corn for over 90% of its feedstock.

Sperling thoroughly describes the production, distribution systems, and use of both conventional and alternative fuels. The book provides a wealth of background information for the reader. He completes his book by evaluating five possible transportation energy paths: (*a*) alcohols from biomass; (*b*) petroleum-like liquids from coal, oil shale, and oil sands; (*c*) methanol from natural gas and coal; (*d*) compressed natural gas from natural gas or coal; and (*e*) hydrogen from solar energy and water. This section provides further insight into problems and potentials for the various fuels to penetrate the U.S. market.

In his conclusion, Sperling outlines the roles that government might play to ensure that the United States has adequate and dependable supplies of transportation fuels that will not degrade the environment or seriously alter our lifestyle.

Sperling's analysis of obstacles to successful development of alternative fuels is rigorous and insightful. This book is highly recommended as a text in courses on resource economics and government and public policy. The book is a gold mine of information that should be on the shelf of every public policy official.

Information on Submitting Manuscripts

1. **Cover letter.** In a cover letter, the author(s) must state (*a*) that the material in the manuscript has not been published, is not being published or considered for publication elsewhere, and will not be submitted for publication elsewhere unless rejected by the *Journal* editor or withdrawn by the author(s); (*b*) that the material in the manuscript, so far as the author(s) knows, does not infringe upon other published material protected by copyright; (*c*) that the employer of the author(s), if any, either does not assert an ownership interest in the manuscript or is willing to convey such interest to the American Agricultural Economics Association (AAEA); and (*d*) that submission of the manuscript gives the AAEA exclusive right to publish, to copyright, and to allow or to deny reproduction of it, in whole or in part. If the applicability of point (*a*) is unclear, the author(s) must explain.
2. **Author's identification.** To protect their anonymity in the review process, authors should not identify themselves in the manuscript. Attach a separate page including the names of the author(s) and appropriate biographical information, as well as the title of the manuscript. Include only the title on the first page of the text.
3. **Typing.** Double-space all material, including footnotes, tables, quotations, and references, on $8^1/_2$-by-11-inch standard weight white paper with margins on all sides of at least $1^1/_4$ inches.
4. **Style.** Follow *A Manual of Style* by the University of Chicago Press as well as previous issues of the *Journal*.
5. **Data and Documentation.** Authors are expected to document their data sources, models, and estimation procedures as thoroughly as possible, and to make data used in their analyses available to other researchers for replication purposes. Submission of appendices, model documentation, and other supporting materials with the manuscript is acceptable in order to facilitate the review process.
6. **Mathematical notation.** Use only essential mathematical notation; it is costly to typeset and may limit the readership. Avoid using the same character for both superscripts and subscripts, using capital letters as superscripts or subscripts, and using overbars, tildes, carets, and other modifications of standard type. Asterisks, primes, and small English letter superscripts are suitable.
7. **Footnotes.** Number footnotes consecutively throughout the paper, not page by page. Type all footnotes, double-spaced, on a page following the article. Footnotes should be only explanatory and not for citations or for directing the reader to a particular work. This information can be incorporated into the text.
8. **References and citations.** Place all references, alphabetized by author, in a list at the end of the paper entitled "References." Only cited works should be included in the reference list. All citations should appear in the text and contain the author's name and page numbers, when necessary. Citations can be inserted parenthetically, e.g., (Doe) or (Doe, p. 5). Specify the date of publication if the same author appears more than once in the reference list, e.g., (Doe 1971, p. 5). If the author's name appears as part of a sentence, a parenthetical reference is unnecessary unless page numbers or a date are needed. A style sheet on references and citations is available from the editor.
9. **Tables.** Place each table on a separate page; double-space all material; omit vertical rules.
10. **Figures.** For accepted manuscripts camera-ready figures must be prepared using professional techniques that are suitable for photographic reproduction. Typescript is not suitable.
11. **Four copies.** Send four fully legible copies to the editor. All copies should be inspected for completeness and quality of reproduction.
12. **Abstract.** Instructions for the preparation of an abstract will be sent when a manuscript is accepted for publication.
13. **Page charge.** Major support for this ***Journal*** comes from page charges of $55 per printed page, or fraction thereof, payable by the supporting institution or granting agency. Payment does not affect acceptance, scheduling, or form of publication. Instructions for payment are sent with galley proofs.

Objective

The American Agricultural Economics Association (AAEA) seeks to further the systematic development of knowledge of agricultural economics in order to improve agriculture and agriculture's contribution to the general economy.

AAEA

—publishes the *American Journal of Agricultural Economics,* the *AAEA Newsletter, Choices*—The Magazine of Food, Farm, and Resource Issues, and, periodically, a *Handbook-Directory* of AAEA members;
—plans and conducts an annual meeting of the membership;
—sponsors awards for Distinguished Undergraduate Teaching, Distinguished Extension Programs, Distinguished Policy Contribution, Publication of Enduring Quality, Outstanding Journal Article, Quality of Communication, Quality of Research Discovery, Outstanding Master's Thesis, and Outstanding Ph.D. Dissertation;
—recognizes prominent agricultural economists as Fellows;
—operates the AAEA Employment Service for agricultural economists.

Membership and Subscriptions

AAEA is a professional society for agricultural economists and others who are interested in agricultural economics. A nonprofit organization, AAEA is committed to furthering knowledge about the economics of agriculture, rural communities, and natural resources.

Membership in the AAEA will bring you *Choices,* the *AJAE,* the *AAEA Newsletter,* and other occasional AAEA publications, permit you to use the AAEA Employment Service, and allows you to attend the annual meetings.

Calendar year dues are: $45, regular members; $22.50, senior (retired and 65) and junior (student) members; $67.50, family members; $150, industry members. Lifetime membership is available for members who are at least 55.

Subscription prices: *American Journal of Agricultural Economics*—$65 per year ($73 overseas); single copies, $14.50. *Choices*—The Magazine of Food, Farm, and Resource Issues—$32.50 per year ($52.50 overseas); single copies, $10. *AAEA Newsletter*—$12 per year ($17 overseas).

For further information about the American Agricultural Economics Association, contact the AAEA Business Office, 80 Heady Hall, Iowa State University, Ames, Iowa 50011-1070 (515-294-8700).

Editorial Communications

All manuscripts and editorial correspondence, except as noted below, should be addressed to:

Peter J. Barry, Editor
Department of Agricultural Economics
University of Illinois
305 Mumford Hall
1301 W. Gregory Drive
Urbana, Illinois 61801

Communications concerning book reviews and books submitted for announcement in the ***Journa*** should be sent to the book review editor:

Dale W Adams
Department of Agricultural Economics
Ohio State University
2120 Fyffe Road
Columbus, Ohio 43210

Editorial Policy

The purpose of the ***Journal*** is to provide a forum for creative and scholarly work in agricultura economics. Thus, acceptable manuscripts should have a relationship to the economics of agriculture natural resources, or rural and community development. Contributions, methodological or applied in the business, extension, research, and teaching phases of agricultural economics are equally en couraged. The ***American Journal of Agricultural Economics*** (ISSN 0002-9092) is published monthl in February, May, August, November, and December by the American Agricultural Economics As sociation, 80 Heady Hall, Iowa State University, Ames, Iowa and printed by Edwards Brothers, Inc. Ann Arbor, MI. Second-class postage is paid at Ames, Iowa, and additional mailing offices. Post master: Send address changes to the American Journal of Agricultural Economics, 80 Heady Hall Iowa State University, Ames, Iowa, 50011-1070.

Subscription

Subscription cost is $65 per year plus foreign postage; members receive copies as part of their mem bership fee of $45 per year.

Preferences of Citizens for Agricultural Policies: Evidence from a National Survey

Jayachandran N. Variyam, Jeffrey L. Jordan, and James E. Epperson

The increasing costs of agricultural programs is raising concern about the future direction of agricultural policies. Data from a nationwide survey on public attitudes toward agriculture are used to examine the structure of citizens' preferences for government involvement in agriculture and especially for policies to protect family farms. Estimates of the influence of economic and sociodemographic variables on policy preferences are computed using a multiple-indicator model. Signs and magnitudes of estimated coefficients lend support to the self-interest theory of voter behavior. Results question economic arguments suggesting altruistic motives as a cause of redistributionary agricultural policies.

Key words: family farms, linear structural relations, self-interest theory.

The rapid growth in U.S. government spending on agricultural programs in recent years has spurred the debate on the future direction of agricultural policies (Cochrane 1985, 1986; Kramer; Blandford; Freshwater). Furthermore, the federal deficit makes the U.S. Department of Agriculture's (USDA) budget a target for reduction. The recent farm crisis has, at the same time, heightened concerns about the stucture of American agriculture, focusing attention on governmental policies to alleviate stress. At issue is the viability of small and medium sized family farms and whether policies should be designed directly for their protection (Comstock, Tweeten). Proponents view the desire to preserve the family farm as a social as well as economic goal (Rausser and Irwin, p. 27; Winters, pp. 11–14). While there is difficulty in defining a family farm (Brewster; Sumner, pp. 285–86) and how to cast family farm support in a concrete and operational form (Winters), the issue remains central to policy discussions (DeLind, Comstock, Strange).

Recently, researchers have examined the agricultural policy process from a political economy perspective (e.g., Petit, Balisacan and Roumasset, Rausser and Irwin). In the political economy framework, governmental decision making is endogenized, responsive to voter and interest group preferences (Silberman and Durden, Gardner). Because agricultural policies represent significant costs to the consumers and taxpayers (OECD), the questions in this context become how far the public is willing to support the general level of transfers and whether support exists for special policies to save the family farm. Pope points to the argument that citizens may feel altruistic toward farm families and hence support income transfer to the agricultural sector. On the other hand, increasing the transparency of policy costs can lead to significant opposition from the cost bearers (Rausser and Irwin). Information on the structure of citizens' policy preferences can be useful to better understand these issues. Moreover, as Schokkaert points out, such information is a prerequisite for any normative judgment on government expenditures for the policies.

Numerous studies have examined preferences for several local national spending categories (e.g., Bergstrom, Rubinfeld, and Shapiro; Lankford; Hewitt; Schokkaert). Despite the need for such studies (Pope, p. 1101), empirical analysis of citizens' preferences for agricultural pol-

The authors wish to acknowledge Stanley M. Fletcher and four reviewers for their helpful comments.

icies are nearly nonexistent. The purpose of this paper, therefore, is to estimate the determinants of citizens' preferences for government involvement in agriculture and, specifically, for policies to protect the family farm.

Policy preferences are investigated in this study using data from a nationwide survey on public attitudes toward agriculture. Most of the previous empirical work on public preference estimation using survey data has relied on responses to a single question concerning the spending category. This approach is problematic given the measurement difficulties associated with survey data. The present study attempts to alleviate the measurement problem by modeling observed responses to multiple questions as imperfect indicators of true preferences. The underlying preferences are then related to the observable characteristics of the individuals and their environment.

Data and Variables

This study uses data from a nationwide mail survey conducted in 1986 by the S-198 Regional Research Project, "Socioeconomic Dimensions of Agricultural Change, Natural Resource Use and Agricultural Structure." The survey was intended to determine public views of changes in the structure of U.S. agriculture. The questionnaire, "Farming in American Life," was developed on a collaborative basis by members of the S-198 technical committee. Pretested questionnaires were mailed to a stratified sample of 10,000 persons representing the U.S. population. The survey contained more than 150 questions including those to determine support of farmers and farm issues, the level of knowledge of farming, and standardized questions to obtain socioeconomic background data. The random sample of persons in the United States was purchased from a national marketing firm (Donnelly Marketing, Nevada, Iowa). The population for which the sample was drawn consisted of a computer-merged list of residential telephone subscribers and automobile owners. Thus, the population should include almost all households in the United States. For example, households which do not list a telephone number and in which no member registers an automobile would be excluded, but most households with unlisted telephone numbers would be included. The sample had eight strata with oversampling in seven states. Thus, appropriate weights were assigned to the respondents to restore equal representation.[1]

To improve the return rate, the questionnaire was mailed three times with three reminder postcards. While a higher return rate would be desirable, the obtained rate was acceptable considering the fact that the sample represents the U.S. population. Including the completed, refused, and deceased questionnaires and correcting for bad addresses, the return rate was 46%. For a more detailed discussion on the development and administration of the questionnaire, data processing, and response rate, see Molnar.

Measurement of Preferences

Survey data are increasingly being used in public preference estimation (e.g., Bergstrom, Rubinfeld, and Shapiro; Gramlich and Rubinfeld; Ferris 1983, 1985; Fisher; Hewitt; Schokkaert; Husted). Other approaches include median voter models based on aggregate data (e.g., Deacon and Shapiro) and micromodels based on referendum data collected through post-referendum survey (e.g., Lankford). However, for national spending categories like agricultural support programs, surveys may be the only source of data to assess citizen preferences.

Many of the previous survey-based studies have used responses to a single preference question as the dependent variable measuring the respondent's preference for the expenditure category under consideration (e.g., Gramlich and Rubinfeld, p. 545; Ferris 1985; Hewitt; Schokkaert). Yet, survey responses are sensitive to the wording, form, and placement of questions in a questionnaire (Kalton and Schuman). Fisher, and Lewis and Cullis discussed this problem in relation to surveys on government public policy. Thus, reliance on response to one question may render the results sensitive to the formulation of the particular question. One solution is to use multiple questions that, while differing in form, wording, and context, are tied to the same underlying concept that the survey intends to measure (Kalton and Schuman).

[1] Seven states were disproportionately sampled to ensure adequate numbers for state-level analysis. The eight strata consisted of 4,000 households sampled nationwide; 1,500 households drawn from Michigan; and 750 households drawn from each of the states of Alabama, Florida, Georgia, North Carolina, Oklahoma, and South Carolina. Weights were computed to restore the proportionate representation of respondents in the strata of the national sample. For each of the eight strata, the weight was equal to the percentage each represents in the U.S. population divided by the percentage in the sample.

The present data provide responses to multiple questions concerning public preferences for government's role in protecting farmers, and especially on policies to preserve the family farm. The nine preference questions directly related to this issue and the corresponding responses are summarized in table 1. In the survey, respondents registered the intensity of their preferences on a five-category Likert scale ranging from strongly agree to strongly disagree.

Although support for farmers is the unifying concept underlying these questions, they differ in wording, focus, and context. For example, only items 4 and 5 have an explicit willingness-to-pay connotation. Items 6, 7, 8, and 9 are more general questions on the government's role in agriculture. The effect of these differences is reflected in the response pattern summarized in table 1. While only 18% of the respondents agreed with the statement that the government should not be involved in agriculture, 44% agreed with the statement that farmers should compete in a free market without government support. Further, there is a decline in the number of respondents who agree with the items on preserving the family farm when willingness-to-pay higher prices is mentioned. This is consistent with previous findings on citizens attitudes toward public expenditure which show that survey responses are sensitive to the inclusion of a "tax price" in the question (Hewitt, p. 488; Lewis and Cullis, p. 26).

Accounting for the wording and focus, the items in table 1 can be embodied in three underlying preference constructs. While the first five items measure a preference for supporting the family farm, items 4 and 5 incorporate the effect of including willingness-to-pay in the questions. To avoid confounding this effect, items 1, 2, and 3 and items 4 and 5 may be linked to two separate constructs. Items 6 to 9 focus on the government's role in agriculture and can be linked to a third construct. The first construct is called "family farm support"; the second, "family farm support with willingness-to-pay"; and the third, "government support."

The hypothesized structure relating the nine items to the three underlying constructs is verified by conducting a factor analysis of the response correlation matrix. The results from

Table 1. Summary of Responses to Preference Questions Used in Analysis

Statement	Frequency and Percent			Skewness	Kurtosis
	Agree	Undecided	Disagree		
1. The family must be preserved because it is a vital part of our heritage.	1,837 (74.6)	269 (10.9)	355 (14.4)	0.900	0.014
2. Obtaining greater efficiency in food production is more important than preserving the family farm.	647 (26.3)	516 (21.0)	1,298 (52.7)	−0.387	−0.736
3. Government should have a special policy to ensure that family farms survive.	1,405 (57.1)	467 (19.0)	589 (23.9)	0.402	−0.752
4. Most consumers would be willing to have food prices raised to help preserve the family farm.	517 (21.0)	481 (19.5)	1,463 (59.4)	−0.546	−0.465
5. Family farms should be supported even if it means higher food prices.	871 (35.4)	640 (26.0)	950 (38.6)	−0.007	−0.918
6. Government should guarantee a minimum price to farmers for their products.	999 (40.6)	497 (20.2)	966 (39.2)	−0.025	−1.074
7. The government should treat farms just like other businesses.	1,306 (53.1)	397 (16.2)	758 (30.8)	0.312	−0.962
8. Farmers should compete in a free market without government support.	1,093 (44.4)	655 (26.6)	713 (29.0)	0.137	−0.829
9. The government should not be involved in agriculture at all.	442 (18.0)	540 (21.9)	1,479 (60.1)	−0.759	−0.016

Notes: Statistics are based on 2,461 observations that were complete with respect to all variables included in the analysis. Skewness and kurtosis have been calculated based on distribution of responses in five categories labeled 1 to 5 representing strongly agree to strongly disagree. For calculation of frequencies, classes 1 and 2, and 4 and 5 have been merged to give agree and disagree, respectively. Percentages may not add up to 100 because of rounding error.

maximum likelihood factor analysis, after retaining three factors and implementing varimax rotation, are presented in table 2.[2] When the rotated factor pattern is interpreted by looking at the highest loadings of each variable, the structure revealed is identical to the hypothesized construct structure. The preference constructs thus identified are specified to depend on a vector of explanatory variables pertaining to the socioeconomic and demographic characteristics of the respondents.

Determinants of Preferences

Individuals are assumed to determine their true preferences under utility maximization over the perceived liabilities and benefits from the proposed policies (Lankford, p. 6). Because the cost-benefit perceptions vary across individuals depending upon their economic and sociodemographic characteristics, such factors should be considered simultaneously to account for the differences in preferences. In previous studies income, education, location of residence, political affiliation, sex, and age were found to be statistically significant (Ferris 1985, Hewitt, Schokkaert). The definitions and descriptive statistics of these and several additional variables considered relevant to agricultural policy preferences are reported in table 3.

Previous literature has given considerable empirical evidence that individual policy preferences reflect self-interest (Deacon and Shapiro, Fisher, Hewitt, Schokkaert). In the present case, the policies are intended to transfer income from consumers and taxpayers to agricultural producers (Gardner, Rausser and Irwin). Therefore, if individuals perceive the policies to be financed by a tax price on income, a pure self-interest model implies a negative coefficient for income. Similarly, to the extent that individuals with a higher education are likely to be better informed about the costs of agricultural support policies, the self-interest model implies a negative coefficient for education.

The private benefit variable *FMINC* (indicating whether a respondent family has income from farming) identifies the potential beneficiaries of the policies; therefore, a positive coefficient is expected for this variable. Because the five residence dummy variables generally contrast consumers against producers (farm residence is the excluded category), these variables also have a private benefit interpretation and negative signs are expected.

The variables *DARATIO* and *AGEDN* are included to capture the dependence of preferences on the degree of farm financial stress in the respondent's area and whether the respondent has been educated in the area of agriculture, respectively. Regional dummies are added, with the Midwest as the excluded category to account for differences in preference after controlling for other locational effects. Two variables are added to indicate the relatively high number of nonresponses to questions on employment status (32%) and farm income (13%). Sex and political affiliation of the respondents exert important influences, and these are discussed in relation to previous literature below. To capture the remaining socioeconomic effects, variables indicating race, religiousness, union membership, employment status, and political activity are also included.

[2] Ascertaining the number of factors to retain based on the likelihood ratio statistic poses difficulties because of the large sample size (Everitt, p. 89). Thus, while only two eigenvalues are greater than one for the response correlation matrix, a chi-square test rejects even a four-factor model as inadequate. A two-factor model resutls in items 1 to 5 and items 6 to 9 having larger loadings on factor 1 and factor 2, respectively, and thus does not separate the effect of the willingness-to-pay aspect of items 4 and 5. A four-factor model merely separates item 3 onto the fourth factor, whereas the rest of the structure is identical to the three-factor model. Thus, a three-factor model gives adequate representation of the structure underlying the responses.

Table 2. Factor Analysis Results After Varimax Rotation

Item No.[a]	Factor 1	Factor 2	Factor 3
1	0.649*	0.203	−0.116
2	−0.488*	−0.306	0.101
3	0.704*	0.164	−0.371
4	0.222	0.713*	−0.008
5	0.447	0.542*	−0.228
6	0.394	0.117	−0.506*
7	−0.114	−0.103	0.529*
8	−0.084	−0.137	0.755*
9	−0.142	0.072	0.515*
Common variance (%)	39.456	24.646	35.898

Note: Asterisk denotes the highest factor loading for the item. For clarity of presentation, the order of factor 2 and factor 3 is the reverse of the order in which they were extracted. See also footnote 2.
[a] See table 1 statements.

Econometric Method

The econometric model involving multiple indicators of unobservable variables may be formulated in the linear structural relations frame-

Table 3. Definition and Description of Variables Used in Analysis

Variable Name	Definition	Mean
Income		
INC	Midpoints of nine income categories ranging from less than $4,999 to $60,000 or more[a]	32159.3
Place of residence (excluded category: farm or ranch)		
LARCITY	1 if over 500,000 in population, 0 otherwise	0.207
MEDCITY	1 if between 50,000 to 500,000 in population, 0 otherwise	0.235
SMACITY	1 if between 10,000 to 50,000 in population, 0 otherwise	0.204
TOWN	1 if under 10,000 in population, 0 otherwise	0.172
COUNTRY	1 if outside of town not on a farm, 0 otherwise	0.131
Education (excluded category: less than high school or some high school)		
HSGRAD	1 if high school graduate, 0 otherwise	0.251
SOMECOLL	1 if had some college, 0 otherwise	0.268
COLLGRAD	1 if college graduate, 0 otherwise	0.256
POSTGRAD	1 if completed postgraduate degree, 0 otherwise	0.121
Political affiliation (excluded category: Republican)		
DEMOCRAT	1 if democrat, 0 otherwise	0.322
INDEP	1 if independent, 0 otherwise	0.406
Sex		
FEMALE	1 if female, 0 otherwise	0.313
Age		
AGE	Age in years	45.17
Agricultural education		
AGEDN	1 if took high school or college agricultural course, 0 otherwise	0.177
Farm income		
FMINC	1 if respondent's family has income from farming, 0 otherwise	0.096
FINCMISS	1 if response to farm income missing, 0 otherwise	0.128
Farm indebtedness		
DARATIO	Average farm debt-to-asset ratio in respondent's state[b]	22.489
Region (excluded category: Midwest)		
NEAST	1 if from northeast, 0 otherwise	0.203
SOUTH	1 if from south, 0 otherwise	0.317
WEST	1 if from west, 0 otherwise	0.195
Employment status (excluded category: employed full-time, part-time, or homemaker)		
UNEMPLED	1 if unemployed, 0 otherwise	0.042
RETIRED	1 if retired or disabled, 0 otherwise	0.192
STUDENT	1 if student, 0 otherwise	0.020
EMPMISS	1 if response is missing, 0 otherwise	0.322
Labor union membership		
UNION	1 if member of a labor union, 0 otherwise	0.188
Political involvement		
POLACT	1 if ever contributed or worked for a political candidate, 0 otherwise	0.392
Religiousness		
RELG	1 if attended religious services during the past year, 0 if not at all	0.723
Race (excluded category: white)		
RACE1	1 if black, 0 otherwise	0.029
RACE2	1 if other, 0 otherwise	0.049

Note: Mean is based on 2,461 complete weighted observations. The standard deviations for the continuous variables *INC*, *AGE*, and *DARATIO* are 17370.2, 15.25, and 6.956, respectively.
[a] Values for the lower and upper open-ended categories were calculated using the range between midpoints of succeeding and preceding categories, respectively.
[b] Source: U.S. Department of Agriculture, Econ. Res. Serv.

work (Joreskog and Sorbom, Everitt). Let η be an $(m \times 1)$ vector of dependent variables related to X, a $(q \times 1)$ vector of explanatory variables through the linear model,

(1) $$\eta = \Gamma \mathrm{hr}\, X + \zeta,$$

where Γ is an $(m \times q)$ coefficient matrix and ζ is an $(m \times 1)$ vector of error terms such that $E(\zeta) = 0$, $E(X\zeta') = 0$, and $E(\zeta\zeta') = \Psi$. The endogenous variables η are not observed directly. Instead they are measured indirectly by Y, a $(p \times 1)$ vector of indicator variables, through the measurement model,

(2) $$Y = \Lambda \eta + \epsilon,$$

where Λ is a $(p \times m)$ construct loadings matrix and ϵ is a $(p \times 1)$ vector of error terms with $E(\epsilon) = 0$, $E(\epsilon\eta') = 0$, $E(\epsilon\zeta') = 0$, and $E(\epsilon\epsilon') = \Theta$. The variables in Y and X are assumed to be mean centered.

The covariance structure of the above model has the form

$$(3) \qquad \Sigma = \begin{bmatrix} \Lambda \;\Gamma\; \Phi\; \Gamma'\; \Lambda' + \Lambda\; \Psi\; \Lambda' + \Theta & \Lambda\; \Gamma\; \Phi \\ \Phi\; \Gamma'\; \Lambda' & \Phi \end{bmatrix},$$

where $E(XX') = \Phi$. The assumptions of the model and the hypothesized relations between variables are specified as restrictions on the parameters in Γ, Λ, Ψ, and Θ.

Imposing the restrictions implied by the relationships between indicators and the preference constructs discussed in the previous section, Λ' has the form:

$$(4) \qquad \Lambda' = \begin{bmatrix} \lambda_{11} & \lambda_{21} & \lambda_{31} & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & \lambda_{42} & \lambda_{52} & 0 & 0 & 0 & 0 \\ 0 & 0 & \lambda_{33} & 0 & 0 & \lambda_{63} & \lambda_{73} & \lambda_{83} & \lambda_{93} \end{bmatrix}.$$

The indicators, except item 3, are specified to load only on one construct to achieve unidimensional measurement (Anderson and Gerbing).[3] For model identification, the scales of the constructs are fixed by the restrictions: $\lambda_{11} = \lambda_{52} = \lambda_{63} = -1$. Thus, the direction of influence of exogenous variables on the constructs can be inferred directly by examining the sign of the respective coefficient estimates. There are no restrictions in Γ. Thus, the model estimates the impact of each explanatory variable on each of the preference constructs. Except Θ_{87}, all the off-diagonal elements in Θ are assumed to be zero.[4] Correlations between the residual errors in Ψ are unrestricted to allow for the influence of additional attributes not considered in the model.

The above model is a special case of the LISREL model (Joreskog and Sorbom). In particular, the explanatory variables are assumed to be fixed, and no structural relations among η are specified. The model can be considered as a system of multiple indicator–multiple cause equations. The full information maximum likelihood estimates of the free parameters in the system can be obtained by fitting Σ to the observed variance-covariance matrix of Y and X (Joreskog and Sorbom).[5]

Empirical Results

The parameter estimates and goodness-of-fit statistics for the model are reported in tables 4 and 5.[6] A 0.05 level of statistical significance is adopted in the following discussion.

The specified measurement structure fits well, as indicated by the estimated construct loadings in table 4. All the loadings are statistically significant, and the measurement R^2 is 0.968. Several goodness-of-fit statistics for the full model are also given in table 4. A simultaneous test of all explanatory variables in the full model (*FM*) against a null model (*MO*) shows that the variables jointly have significant explanatory power ($\chi^2(MO\text{-}FM)$ with 90 degrees of freedom = 677.2). The other goodness-of-fit statistics, including the structural R^2 (0.359), root mean squared residual (0.021), and the adjusted goodness-of-fit index (0.916), also point to a good model fit.

The estimated coefficients of explanatory variables and the associated t-ratios are presented in table 5. The parameter estimates in

[3] Item 3 is specified to load on the third construct (government support) because of the reference in the item to the need for special government policy (table 1). This specification retains the meaning of the constructs and gives a better model fit. The sensitivity of parameter estimates to this specification was tested by setting $\lambda_{33} = 0$ and found to be negligible.

[4] It is difficult, a priori, to specify correlated measurement errors. *LISREL* calculates modification indices which provide a clue. In the present case, in a base line model with diagonal Θ, θ_{87} had the largest modification index. Based on the nature of items 7 and 8 (table 1) correlated measurement error seemed plausible. Thus, θ_{87} is unrestricted in the final model. Close agreement with parameter estimates in the base line model indicated that the reported results are not sensitive to this specification.

[5] Analysis is based on the correlation matrix, and therefore, the coefficient estimates can be compared across variables (Saris and Stronkhorst, p. 256). Maximum likelihood estimation and inference assumes independently and multivariate normally distributed Y given X. Univariate skewness and kurtosis within the range -1.0 to $+1.0$ (table 1) indicates maximum likelihood results would be robust in the present case (Muthen and Kaplan, p. 187; Bentler and Chou). Further, the test of multivariate normality based on Mardia's coefficient of relative multivariate kurtosis (Bentler and Chou) did not reject the null hypothesis that the variables follow a multinormal distribution.

[6] Following Babakus, Ferguson, and Joreskog, the model was reestimated using polychoric correlations. The results were similar to those reported in their simulation study. While the parameter estimates based on polychoric correlations had higher t-ratios, all the goodness-of-fit statistics showed a poorer fit. Therefore, results based on product-moment correlations are reported here.

Table 4. Estimates of Construct Loadings and Model Goodness-of-Fit Statistics

Parameter	Estimate[a]	Parameter	Estimate[a]
λ_{11}	-1.000^b	λ_{52}	-1.000^b
λ_{21}	0.852	λ_{63}	-1.000^b
	(25.669)		
λ_{31}	−0.620	λ_{73}	0.552
	(−17.933)		(17.079)
λ_{33}	−0.569	λ_{83}	0.806
	(−16.615)		(24.258)
λ_{42}	−0.653	λ_{93}	0.629
	(−21.326)		(19.700)

Number of observations = 2,461
Measurement $R^2 = 0.968$
Structural $R^2 = 0.359$
Goodness-of-fit index = 0.978
Adjusted goodness-of-fit index = 0.916
Root mean squared residual = 0.021
χ^2 for full model with 202 degrees of freedom = 1062.77
χ^2 for null model with 292 degrees of freedom = 1739.97[c]

[a] The asymptotic t-statistics are given in parentheses.
[b] Construct loading is restricted to equal −1.0 for identification.
[c] The null model is obtained by restricting all elements in Γ to zero.

columns 2, 3, and 4 represent the relative impact of explanatory variables on the preference constructs "family farm support," "family farm support with willingness-to-pay," and "government support," respectively.

Income is a significant determinant of agricultural policy preferences. The coefficients for income are significant for all three preference constructs. The negative sign indicates that as income increases, support for special policies to protect the family farm as well as government intervention in general declines. The negative coefficients for income are similar to the micro findings of Gramlich and Rubinfeld (pp. 545–47) and Husted for other redistributive spending categories.

All the residence variables have negative and statistically significant coefficients with respect to η_2. This shows that urban, town, and country dwellers have strong negative preferences for agricultural policies that may lead to higher food prices. The impact of residence variables on η_3 is not as strong but indicates more opposition to government support for agriculture coming from town and country residents. The private benefit variable *FMINC* has a positive and statistically significant coefficient on η_1. Insignificant coefficients for *FMINC* on η_2 and η_3 were unexpected. However, this may reflect the presence of residence variables which have farm or ranch as the excluded category. When the model was reestimated after dropping all residence cate-

[a] Here, η_1, η_2, and η_3 represent unobservable preference constructs and are called "family farm support," "family farm support with willingness-to-pay," and "government support," respectively.
[b] Single and double asterisks denote significance at the 1% level and 5% level, respectively.

gories, *FMINC* exhibited a significant positive impact on η_2. The coefficient on η_3 was positive but insignificant. This may be indicative of the commodity-specific nature of government programs as well as farmers' dissatisfaction with government policies.

The coefficient estimates for almost all categories of higher education are negative and significant. Estimates on η_3 show a monotonic trend implying greater opposition to government support with increasing education. On the other hand, coefficient estimates for *AGEDN* are insignificant, indicating that no differences in preferences exist between those who had agricultural courses in high school or college compared to those who did not.

The estimated impact of *DARATIO* indicates that the degree of local farm financial stress has no significant impact on preferences for policies to protect family farms. The parameter estimate for *DARATIO* on η_3 is negative and significant and may reflect the view that government intervention itself is a source of greater financial distress. The coefficient estimates for regional dummies indicate significant differences in preferences between the Midwest and other regions. Individuals from the Northeast are likely to be most supportive of a governmental role in agriculture, while those from the West are least likely to be so. This result is similar to Fisher's finding on the regional differences in preferences for the broader category of spending on all government services. Individuals from the Northeast, South, and West are also more likely to oppose policies that may lead to higher food prices compared to those from the Midwest. The above conclusions remained unaltered when *DARATIO* and regional dummies were alternately dropped to estimate the pure impact of the other.

Because the survey did not include questions on actual or perceived tax rates, this information could not be used. However, following Hewitt, an attempt was made to include a quantity variable, namely the total government payment (*GPAY*) to the agricultural sector in the respondents' state in 1985 (USDA). Parameter estimates for *GPAY*, after dropping *DARATIO* and regional dummies, showed a significant impact only on η_2, and the effect was positive. This may indicate a positive preference for respondents from areas with a relatively large agricultural sector. This view is supported by the performance of a variable pertaining to the share of total personal income in the respondent's state from farming and agricutural services (*PAGINC*). When the coefficients for *PAGINC* were estimated after excluding *DARATIO* and regional dummies, the effect was exactly the same as that of the *GPAY*. Both *GPAY* and *PAGINC* had relatively strong correlation with each other as well as with *DARATIO* and the regional dummies. When included jointly, the parameter estimates for all these variables were unstable. Therefore, *GPAY* and *PAGINC* are not included in the final model.

Political affiliation is shown to have a significant impact on policy preferences as noted in previous studies (Fisher, Francken). The present results are comparable to the findings of Fisher (pp. 543–45) and Husted, and indicate that Democrats and Independents are more likely to favor the support policies compared to Republicans. The parameter estimates for *POLACT* indicate that politically active individuals are opposed to government intervention in agriculture.

Among socioeconomic and demographic variables, effects of sex and age are notable. The coefficient estimates for sex are positive and significant suggesting that women are considerably more in favor of saving the family farm and supporting agriculture than men. Hewitt obtained similar results for other spending categories and points out that this may be indicative of the different voting pattern observed among women. The negative impact of age on preference for government support is similar to the results of Ferris (1983) and Hewitt. As age increases there is greater disapproval of governmental role in agriculture. Yet, there is a greater approval of policies to preserve the family farm. This may arise because older people have more cultural attachment to the concept of the family farm.

Membership in a labor union has a positive impact on preference for government support as evidenced by the positive and significant coefficient for *UNION* on η_3. Further, while unemployed individuals are more likely to favor government support, other employment status variables show no significant influence on this construct. With regard to preserving the family farm, the difference in preference between union and nonunion individuals disappears when willingness-to-pay is introduced. Similarly, under willingness-to-pay, there is no difference in preference for preserving the family farm based on the employment or the racial status of individuals. While in all three cases there is no difference in preference between blacks and whites, individuals from other races exhibit positive preference for government support compared to

whites. The coefficient estimates for *RELG* are insignificant across the three preference constructs indicating that, controlling for other socioeconomic effects, religiousness is not a significant determinant of preferences. Political affiliation, political involvement, and religion are probably all endogenous. However, when the model was estimated after excluding these variables individually and jointly, there was no reversal in sign or change in inference for the coefficients of the remaining variables.

The present results are striking compared to many previous studies on public preferences in that economic, sociodemographic, and political variables are all significant with theoretically plausible signs (Fisher p. 529; Ferris 1983, 1985). The consistency and the relatively larger magnitudes of the impacts of income, education, political affiliation, and sex across the preference constructs are especially notable. By considering preferences for family farm support with and without willingness-to-pay, the model is able to reveal shifts as well as consistency in the impact of the explanatory variables in a parsimonious manner.

Concluding Comments

This study involved the use of data from a national survey of public attitudes toward agriculture to estimate the structure of citizens' preferences for policies to preserve the family farm and support agriculture. While the distribution of responses to particular survey questions indicates considerable support for the policies, the support is shown to erode when the questions are asked in a different context. Therefore, a latent variable formulation is used to control for the measurement error and estimate the impact of economic, sociodemographic, and political variables hypothesized to influence the underlying preferences.

Taken together, the results on the impact of income, education, residence, and farm income support the view that individuals act in their self-interest in deciding preferences for government policy in agriculture. These results cast doubt on the economic arguments suggesting altruistic motives of citizens as a cause of redistributionary agricultural policies. The economic variables perform as predicted by the self-interest theory even on the widely discussed issue of preserving the family farm. The results show the degree to which urban, town, and country dwellers are averse to the policies that may lead to higher food prices. The residence variables and variables indicating employment status, union membership, and race exhibit context-specific influence with regard to preferences for protecting the family farm, with their impacts sensitive to the mention of willingness-to-pay higher food prices. These results lend support to the suggestion that increasing the transparency of policy costs can spur the policy reform process.

With regard to government support, higher income, residence in town or country, higher education, higher age, residence in the West, and political activity all indicate greater opposition. The estimated impacts of sex and political affiliation indicate that women and Democrats and Independents tend to favor the support policies compared to men and Republicans, respectively.

Since the study is based on a one-time cross-sectional survey, the dynamic aspects of preferences could not be addressed. This may be important inasmuch as policy preferences could be influenced by changing economic and political events (Lewis and Cullis, p. 29). In particular, the effect of variables measuring financial distress and psychological variables indicating policy perceptions may be important and can be adequately studied only with repeated samples. The present results on the effect of financial distress must therefore be interpreted with caution. Future research on agricultural policy preferences would also benefit from information on perceived tax prices, and well-structured questions on willingness to pay.

On a final note, if a policy objective is to support the small or family farm or agriculture in general, the profile of those most likely to oppose such policies are males with high levels of income and education. Interestingly, that profile characterizes the majority of the graduates of land grant universities: males with a college education and above-average earnings. It appears that those with whom land grant universities have the most direct contact would not support policies to aid family farms, however defined. Further, the exposure to agriculture in course work at the high school or college levels had no effect on the degree of support for agricultural programs. Although only a small percentage of students at a land grant university are exposed to agriculture, the mission and the raison d'être of land grant universities may not adequately be conveyed to the student body.

A Policy Analysis of China's Wheat Economy

Catherine Halbrendt and Conrado Gempesaw, II

This paper examines the impacts of China's historical and anticipated future reforms on its domestic wheat economy and how it affects the import demand for wheat using a stochastic coefficient regression method. The results strongly support the hypothesis that producers and consumers in the post-reform era were responsive to a less controlled economy. Furthermore, the higher import forecasts indicate that China will interact more with the world wheat market.

Key words: China, policy, stochastic coefficients, wheat.

The world wheat market is highly dependent on the trade behavior of the major centrally planned economies, such as China. During 1961 to 1987, China's wheat imports were substantial, averaging about 9.3% of total world traded volume annually (USDA). However, since 1978 China's import behavior has added significant uncertainty to the world wheat market (Ralston). China import levels reached a historical high of 13.57 million tonnes in 1980, but dropped to about 5 million tonnes in 1985 and 1986 (Carter and Zhong). The import fluctuations from 1978 to 1986 can be attributed to the new reforms since 1978, particularly the decentralization of farm household decision making and the liberalization of markets for surplus commodities. Recently, according to *Farmline,* in order for China's farm sector to keep up with the growing population and rising incomes resulting from economic reforms, China had to increase its wheat purchase in 1987 to 13.5 million tonnes. By virtue of having 25% of the world population and limited new arable land, China will continue to play a major role in the world's wheat market.

This article examines the impacts of China's historical and anticipated future reforms on its domestic wheat economy and the import demand for wheat. Specifically, this paper attempts to assess China's wheat policies before and after the reforms of 1978 and to forecast domestic wheat production, consumption, and imports. The following sections describe the model specifications, rationalize the stochastic coefficient regression approach, present the empirical results, and consider their implications.

Model Development

The China wheat model in this study consists of three components. The first component models the production relationships with separate yield and acreage response equations. The second part represents the consumption side and distinguishes between urban and rural residents' consumption behavior. The third component captures the trade relationships via an import behavioral equation. The development of the model is based on past studies on China by Tang and Stone, Noh, Yang, Ralston, and Carter and Zhong.

The China wheat model equations are specified as follows (see table 1 for variable definitions):

$$(1) \quad WHEATYLD = \beta_{10} + \beta_{11}{*}FERT\_HA + e$$

$$(2) \quad WHEAT\_HA = \beta_{20} + \beta_{21}{*}RWHTINDX + \beta_{22}{*}RRAPPRC + e$$

$$(3) \quad URBWHCON = \beta_{30} + \beta_{31}{*}[WHEATPRD + WHEATIMP] + \beta_{32}{*}RWHTINDX + e$$

Catherine Halbrendt and Conrado Gempesaw, II, are an assistant professor and an associate professor, respectively, in the Department of Food and Resource Economics, College of Agriculture, University of Delaware.

(4) $RURWHCON = \beta_{40} + \beta_{41}*WHEATPRD + \beta_{42}*RWHTINDX + e$

(5) $WHEATIMP = \beta_{50} + \beta_{51}*WHEATPRD + \beta_{52}*R\_WPRAT + \beta_{53}*FOR\_EXCH + e.$

Wheat Production

Before 1978, planned crop acreage and production quotas were mandated to ensure adequate grain supplies. The 1978 reforms continued to use quotas to ensure sufficient supplies and also adopted several new policies to stimulate higher production: (*a*) price incentives in which the quota prices for grain were increased by 20%, and the above-quota prices were set 50% above the quota prices in 1979; (*b*) increased allocation of chemical fertilizers, diesel oil, and other inputs to agricultural production (Carter and Zhong); (*c*) a restructuring of agriculture to encourage farm investment and concentration of production to capture economies of scale; (*d*) tenure on agricultural land leases was extended in 1980 from five to fifteen years and further extended in 1987 to fifty years in some areas.

As a result of the market-oriented policy, the period since the 1978 reforms was characterized by substantial increases in productivity. From 1980 to 1987, aggregate wheat production increased over 6.8% annually despite almost constant sown acreage. Sown acreage stabilized because of increasing demand on land for competing farms and nonfarm use, while wheat yields per acre increased 6.9% annually. These higher yields were attributed to increased fertilizer use, better seed varieties, and improved management efficiency. The government distributes inputs such as fertilizer at favorable input-to-output price ratios (USDA). Continued production increases at these recent rates appear unlikely because land holdings are undercapitalized, overly dispersed, and suffer from inappropriate technology and managerial forms (Calkins). The leadership since the 1978 reforms will probably rely more heavily on production targets in order to ensure adequate consumer supplies and reduce reliance on the world markets (Barker, Sinha, and Rose).

Previous grain production projection models of China used simple equations, time-series, and econometric models. Tang and Stone's model was formulated equating output index to factor productivity and weighted input indexes. The fundamental problem with Tang and Stone's model, as shown by the high differential between actual and projected values, was the arbitrary weights assigned to the input indexes and productivity factors. Noh projected China's grain production with a quadratic time trend model and an ARMA (1, 1) model. Noh's projection was systematically low when compared to the actual figures. Carter and Zhong's grain production model contained separate acreage and yield equations. Their approach used population as the key policy variable in the sown acreage response equation. Their yield equation was specified as a function of a price and a time variable that was a proxy for technology. The wheat production model in this study also has separate yield and acreage equations. The equations are specified to incorporate some of the positive aspects of the previous production models and include economic variables, such as substitute price, fertilizer application rates, institutional changes, and other factors that were not explicitly specified in the previous studies.

The major contributor to growth in agricultural productivity has been the substantial increase (67%) in the use of chemical fertilizer for grains since 1978 (Stone, Carter and Zhong). Fertilizer quality and efficiency of application have also improved significantly. Thus, the general model of China's wheat economy begins with a simple yield equation in which yield is a function of fertilizer application rate per hectare. Variable definitions and descriptive statistics are shown in table 1. The conventional hypothesis of an input's contribution to productivity implies a positive β_{11} term.

Land in wheat production remained at approximately 29 million hectares throughout the 1960–87 period. One factor which may have influenced acreage response to the 1978 reforms is the price ratio of grain to cash crops (Walker). The alternative crop for such land is rapeseed (Tuan, private communication, 1989). When grain production increased dramatically and the double-price system was established, producers could take advantage of nonmandatory deliveries of rapeseed *vis-à-vis* grain crop prices at lower procurement prices and shift land to rapeseed (Carter and Zhong). Therefore, variations in wheat plantings after the 1978 reforms are hypothesized to reflect the relative prices of wheat and rapeseed. No such relationship is hypothesized prior to 1978 because the government purchased grain at fixed prices. Thus, the wheat acreage equation can be specified as a function of real wheat and rapeseed prices with a positive sign expected for the β_{21} term and negative sign for the β_{22} term.

Table 1. Data Summary—China Wheat Economy, Selected Years

Variable	Description	1960	1978	1985	1987
FERT_HA[2]	Fertilizer use (kg/ha)[5]	30	440	655	737
FOR_EXCH[1]	Foreign exchange earnings (US $00 million)	18.6	97.5	273.6	399
RRAPPRC[4]	Real rapeseed price (yuan/tonne)		3.48	2.78	2.39
RURWHCON[3]	Rural per-capita wheat consumption (kg/year)	24.6	48.7	90.1	90.3
URBWHCON[3]	Urban per-capita wheat consumption (kg/year)	30.3	51.6	82.9	83.4
RWHTINDX[1]	Real wheat price index (base year 1950)	93.3	99.0	72.2	72.0
R_WPRAT[2]	Rice/wheat world price ratio	2.13	3.29	1.72	1.66
WHEATIMP[2]	Wheat imports (000 tonnes)	1,949	8,047	6,600	12,500
WHEATPRD[2]	Wheat production (000 tonnes)	20,960	53,840	85,810	87,000
WHEATYLD[2]	Wheat yield (kg/hectare)	782	1,845	2,937	3,007
WHEAT_HA[2]	Planted wheat acreage (000 hectares)	27,294	29,183	29,218	28,930

Wheat Consumption

Per-capita wheat consumption in China's rural areas has been consistently lower than per-capita grain consumption in urban areas. Such skewness in food availability is common among developing countries. Before the 1978 reforms, with negligible gains in domestic wheat production per capita, deficit years saw sharp reductions in rural per-capita consumption, and increased wheat imports were principally used to maintain urban rations (Barker, Sinha, and Rose). After the reforms, the large gains in wheat productivity have enabled rural per-capita consumption to increase dramatically, closing the gap between rural and urban consumption. Furthermore, China has allowed incomes and relative market prices to determine food consumption patterns (OECD).

Past studies dealing with grain consumption models for China have one basic limitation. As noted by Carter and Zhong, these studies (Tang and Stone, Noh) lacked a strong theoretical linkage between consumption and key economic variables such as prices and income. Based on these limitations, Carter and Zhong's rural and urban grain consumption equations were specified as a function of per capita income and lagged consumption. Lagged consumption was used to reflect the influence of consumption habits on current consumption. However, the lagged consumption variable is not used in this study for the following reasons. In Ishikawa's survey on food grain consumption, the results underscored the economic importance of the turning point of direct grain consumption as economic development improves. In the case of Taiwan, he noted that direct grain consumption peaked in 1969 and declined thereafter. China's current economic development stage is approaching, if not at, the stage achieved by Taiwan in the 1960s (Tuan, personal communication 1988; Ralston). For some fairly developed regions, direct consumption of grain has already begun to decline (Walker).

This study's wheat consumption equations include economic variables such as income, price, and separate urban and rural per-capita consumption. The equations are also formulated to use the available statistical data since the economic reform was implemented. Separate urban and rural per-capita wheat consumption equations are specified to test the effects of prices and available supply on changes in wheat consumption. Urban per-capita wheat consumption is specified as a function of available supply (domestic production plus imports) and the real price of wheat; β_{31} is hypothesized to be positive, while β_{32} is hypothesized to be negative.

Per-capita rural wheat consumption is specified as a function of wheat price and production. Instead of using the income variable as an explanatory variable, rural consumption is hypothesized to be positively related to production because rural consumption depends on the residual amount after fulfillment of the quota rather than on income. A negative relationship between rural per-capita consumption and price is anticipated.

Wheat Imports

China's grain imports (of which 85% have been wheat) have increased substantially since 1960. This is attributed in part to grain production dropping by 50 million tonnes due to perverse economic incentives and poor weather from 1958 to 1960. By 1965, grain production recovered to the pre-1958 level and continued to increase into the late 1970s. During that same period, grain imports averaged five million tonnes, due to government intervention by restricting food consumption through rationing in the urban areas and obtaining target supply through procurement quotas. However, in 1980, 13 million tonnes of wheat were imported and remained at that level until 1982. The record import levels occurred even though China was setting new production levels. According to Carter and Zhong, the large quantity of grain imports after 1978 is attributable to the reforms of 1978.

In the past, China's economic goals were aimed at production. Provincial self-sufficiency in grain was promoted regardless of economic efficiency. These types of policies proved to be self-defeating, and since 1978 major changes occurred to offset the differences between consumption and production. Producers were allowed to reallocate their resources to reflect comparative advantages and produce more profitable crops. Consumers could purchase grain on the free market. The consequences that ensued from the 1978 reforms had varying influences on wheat imports.

According to Ralston, grain import needs will also be influenced by policies encouraging production of other crops, such as cotton, sugar, and oilseeds. These crops have been more expensive to import. All these policies together influence the production of wheat. Moreover, the production quantity will be supplemented with imports to meet consumption targets.

During the 1960s world grain prices and China's terms of trade favored the export of rice and imports of relatively cheaper wheat. Wheat imports were periodically curtailed due to severe balance-of-payments problems. Record levels of domestic production in 1983 and 1984 initiated a downward trend in China's wheat imports. This downward trend has already reversed its course recently because of slower growth in domestic production and pressures from increasing population. The wheat import equation is specified as a function of foreign exchange earnings, ratio of world wheat price to world rice price, and current year's production.

Wheat imports are hypothesized to increase as foreign exchange earnings permit and to fall as world wheat prices rise relative to world rice prices. Imports are expected to be inversely correlated with the current year's domestic production.

Data Definitions and Sources

Annual time-series data covering the period 1960–87 were used to estimate the five equations discussed above. All the data except urban and rural per capita consumption, the wheat price index, the rapeseed price, and the general price index were taken from USDA, "China: Situation and Outlook Series." Rural and urban per-capita consumption data were calculated using data on per-capita cereal availability and percentages of urban and rural grain consumption (Piazza). The real wheat price index was calculated by using the purchasing price index of wheat deflated by the general price index. The rapeseed price was taken from the December 1988 issue of *China Quarterly*. Any remaining data were taken from various publications of the China's State Statistical Bureau (see footnotes, table 1).

Estimation and Forecast Method

The general objective of this study is to demonstrate whether the 1978 economic reforms influenced the structure of China's wheat economy. Conventionally, dummy variables are used in standard fixed coefficient estimating methods such as ordinary least squares (OLS) to capture policy impacts on the structure of a sector. However, some limitations are encountered when using this conventional approach. The first problem is the difficulty in defining the stages of the policy's impact, i.e., the exact timing of when the policies are announced, when they are in full effect, and how they are fine tuned. Second, the fixity of agricultural assets and inelastic supply and demand contrast with the abrupt shocks that occur when dummy variables are used. Third, a fixed coefficient estimation method assumes constancy in the marginal contribution of causal factors which is restrictive when evaluating the impacts of China's evolving policies.

Because there were no strong theoretical grounds for choosing linear specifications and gains from the economic reforms were not sys-

tematic as evidenced by the changes in the growth rates, this study chose the stochastic coefficient regression approach (SCM) developed by Swamy and Tinsley (see appendix). Other reasons for choosing the SCM approach included functional form specifications (which was stated as a source of uncertainty in Van der Gaag's study on China), aggregation effects, changes in tastes and technology, ability to accommodate changing structural parameters due to a new governmental regime, and the ability to generate time-dependent elasticities (Conway).

Another objective of this study is to forecast China's future production, consumption, and imports. Conway; and Conway, Hrubovcak, and Le Blanc conducted several studies supporting the general superiority of SCM over fixed-coefficient methods in forecasting. In this study, two measures similar to Conway's were used to test the relative forecasting efficiency of SCM over fixed-coefficient method. First, out-of-sample forecasts for the 1985–87 period from SCM and OLS models, reestimated for the 1960–84 data, were compared. Second, root mean square error (RMSE) statistics of the out-of-sample forecasts were also compared. The results in table 2 show that the SCM has much smaller root mean square errors for each of the model's equations. Table 3 shows the results of the out-of-sample forecasts. The SCM method was definitely superior because almost all of the forecasts were closer to the actual values.

Estimation Results and Discussions

Parameter estimates of this study's model are presented in table 4. Elasticities of selected variables for the 1970–87 period are shown in table 5. All parameters have the expected signs. The estimated parameter on (*FERT_HA*) of the yield equation had the expected response and the elas-

[b] t-statistics are in parenthesis.

ticities of yield with respect to fertilizer application through time increased from 0.7 to 0.9 (table 5). The more elastic trend is logical because fertilizer quality (as cited by Stone) improved greatly since the 1978 reforms. The elasticities of the acreage planted equation with respect to prices since 1978 were in general very inelastic. The inelastic responses could be attributed to commitments to fulfill governmental contracts, thus decreasing land base due to nonagricultural use and other more lucrative enterprises.

The rural and urban per-capita consumption equations showed the expected responses to wheat price and supply with urban consumers slightly more responsive. Elasticities of the responses of urban consumers to wheat prices became more inelastic in recent years, declining from −0.2 to −0.055 for the 1970–87 period. The post-1978 reform elasticities were slightly higher than the price elasticity (−0.005) Ito, Grant, and Wesley estimated for China's rice. This trend toward more inelastic responses of consumption to prices reflects the amount of cereal grains already in

Table 5. Estimated Elasticities of China Wheat Economy for Selected Variables and Years

Year	Yield/ Fert._ha	Acreage/ Wheat Price	Urban Consumption/ Wheat Price	Wheat Imports/ Price Ratio	Wheat Imports/ Foreign Exchange

1987	0.911	0.273	−0.055	0.116	1.844

the Chinese diet. Sixty percent of the Chinese diet by weight is currently comprised of wheat and rice. Based on Ishikawa's study on developing countries, this trend suggests that urban consumers could be approaching the peak consumption level of grains.

All the parameter estimates of the wheat import equation had the hypothesized signs. Foreign exchange is shown to have an impact on wheat imports. The range of elasticities between wheat imports and foreign exchange earnings was wide, ranging from 0.3 to 2.2 (see table 5). The elasticities were greater than one in the mid-1980s and generally less than one before the 1978 reforms. This trend could indicate that the Chinese planners are becoming more open to international trade and market forces.

The estimated parameter on (*R_WPRAT*) was positive suggesting that the Chinese planners have considered relative world rice and wheat prices when making import decisions. The elasticities were generally positive but inelastic. During the post-1978 reform period, the elasticities were lowest, suggesting that the planners were more responsive to consumption preference rather than maximizing foreign exchange earnings. Historically, to maximize foreign exchange earnings, China has exported expensive rice when the world price was high, disregarding domestic preference for rice (in the southern region), and substituting less expensive wheat when the world wheat prices were relatively lower. The lower elasticities indicate that Chinese planners might have been less inclined to continue these past practices.

Wheat Economy Projections

The estimated model of this study was used to project China's wheat economy performance from 1988 to 1991. In order to project yields, acreage planted, consumption, and imports, the application rates of fertilizer, domestic prices of wheat and rapeseed, foreign exchange earnings, and world prices of rice and wheat must be projected first. For comparison, two scenarios were assumed. One was based on the annual growth rates of the current regime assuming this will continue into the future; the other scenario was based on projections by Carter and Zhong, USDA, and Stone.

For the yield equation, fertilizer application rates were assumed to continue to grow at 6% annually for the current regime. According to Stone, the average application rate in China is still low compared to Japan and Korea. Roughly two-thirds of China's farmland is seriously underfertilized, especially with potassium and phosphorus; it can benefit considerably from higher application. Recently, the Chinese government reinforced the incentive system allowing farm households to buy more and better quality fertilizer at fixed prices (USDA). Based on this, the alternative scenario was based on a higher fertilizer application growth rate (8%).

For the acreage planted equation, the current regime prices for wheat and rapeseed were assumed to continue at annual rates of negative 3.4% and 4.0%, respectively. According to Carter and Zhong, the price ratio of grain to major cash crops is likely to increase slightly in the foreseeable future. Their study indicated that the actual grain price will increase about 5% annually until 1990 as more grain goes through the free market. Nominal rapeseed price rose 60 to 80 yuan per tonne in 1988 (Sincular). As such, the real wheat and rapeseed prices were assumed to grow moderately at 1.5% and 1%, respectively, in the alternative scenario. The same assumptions on wheat prices were used in the consumption equations. Because of the stronger demand for wheat on the world market in recent years, this study's current regime and alternative scenarios assumed that the ratio of rice price to wheat price will increase at the same rate versus a declining rate prior to 1987.

Foreign exchange earnings grew at an annual rate of 17% since the 1978 reforms. Based on USDA expectations, foreign trade should continue to increase but at a lesser rate. Thus, a 10% annual increase in foreign exchange earnings was assumed for the alternative scenario. To capture the recursive character of the model, the predicted values of the endogenous variables were used in other equations using those variables as explanatory factors. Projections for yield, acreage planted, consumption, and imports are shown in table 6.

The forecasts show that if China can sustain its current productivity (the current regime scenario), yield per hectare would increase 7.6% annually, while acreage planted would increase slightly. With increasing consumption predictions, imports would increase to a record high of 35 million tonnes. The alternative scenario assumed a higher fertilizer application rate which resulted in a much higher yield forecast of 8.7% annual growth. The higher productivity along with minimal change in planted acreage forecasts resulted in a much lower import forecast than the current regime's scenario.

Table 6. China's Wheat Economy Forecasts Using Stochastic Coefficient Method

	1988	1989	1990	1991
Wheat yield forecasts (kg/hectare)				
Current regime	3,294.89	3,506.63	3,701.02	3,941.51
Alternative	3,322.62	3,567.33	3,975.69	4,272.65
Wheat acreage forecasts (thousand hectares)				
Current regime	29,562.8	29,592.8	29,624.3	29,655.8
Alternative	29,558.4	29,551.3	29,539.8	29,532.7
Rural per capita wheat consumption forecasts (kg/year)				
Current regime	96.3	101.9	107.2	113.6
Alternative	96.9	103.3	113.9	121.6
Urban per capita wheat consumption forecasts (kg/year)				
Current regime	90.4	97.7	105.5	114.8
Alternative	90.2	94.5	102.5	109.1
Wheat imports forecasts (thousand tonnes)				
Current regime	17,953.1	22,669.9	28,670.6	35,752.1
Alternative	15,313.6	16,674.7	17,234.7	18,882.7

Note: Current regime scenario: the exogenous variables annual growth rates were based on the current regime's growth rates. Alternative scenario: the exogenous variables annual growth rates were based on other studies assumption/projections.

Forecasts of this study and past studies are compared in table 7. This study's yield forecasts are comparable to Carter and Zhong's of 0.73 to 0.97 tonnes per hectare. The yield forecasts seem plausible because Chinese authorities still embrace the self-reliance, self-sufficiency food policy. In 1987, China's nitrogen fertilizer imports increased 100% from the previous year, supporting the hypothesis of continued emphasis on self-sufficiency in food production (USDA). The moderately increased planted wheat acreage forecasts under the alternative scenario are consistent with USDA assumptions. The likelihood of increases in future planted wheat acreage is plausible based on statements by Chinese authorities regarding the allocation of additional resources to reclaim land (USDA).

This study's model predicts consumption to grow about 5% to 7% annually for urban and rural residents. This rate is much lower than the period since the 1978 reforms. However, it is consistent with the USDA report of declining growth rate of grain consumption due to population and feed use increases. The consumption levels predicted were comparable to Carter and Zhong's study (table 7).

Finally, the results of this study indicate that imports will increase slowly but consistently into the 1990s. The alternative scenario projections for imports were much smaller than for the current regime scenario. Up to eighteen million tonnes of imports were projected to occur in 1991. This import level, according to Carter and Zhong, was not in conflict with the government's policy toward self-sufficiency and is well within China's capability in terms of transportation and balance of payments. The increasing import levels are consistent with projections by Carter and Zhong and by Ralston (see table 7). Moreover, a USDA outlook report in June 1988 stated that coastal urban areas are likely to import sizable quantities of wheat for human consumption.

Concluding Comments

China's agricultural sector growth has had an impressive record since market and price reforms were initiated in 1978. The results of this study strongly support the hypothesis that producers and consumers in the post-reform era were responsive to a less controlled economy. Regarding imports, the Chinese authorities were shown to be responsive to world prices, although they were constrained by foreign exchange earnings. At the same time, the estimated elasticities revealed the changing responsiveness of producers, consumers, and Chinese authorities' to market signals throughout the 1970–87 period. Estimated elasticities of consumption and planted acreage to prices have become more inelastic in recent years suggesting limited flexibility to respond to alternative enterprises by producers, and the increasing preference of consumers to improve their diets with more meat protein (USDA). The trend toward more inelastic responses by Chinese plan-

Table 7. Comparison of China's Grain Forecasts, Selected Variables

Variable	Product	Study	Estimation Period	Relative Change 1987–90	Assumptions

Table 7. Continued

Variable	Product	Study	Estimation Period	Relative Change 1987–90	Assumptions
	wheat	Halbrendt and Gempesaw	1960–87	−15.1	See projections section for the assumption for the import equation
				−3.7	See projection section for the assumption for the import equation

ners to the world rice over wheat price ratio suggests more attention has been given to consumer preferences rather than earning foreign exchange to subsidize industrialization. The projected import forecasts of this study are similar to Carter and Zhong's and Ralston's grain projections.

Results from this study indicate that China will interact more with the world economy through higher imports. Exporters can use this information to plan their export strategies. Finally, future agricultural policy will continue to expand the role of market forces in the Chinese economy. However, the government will not cease to play an important role in influencing production decisions to meet their planned targets (Ralston, USDA).

SCM Approach

Following Swamy and Tinsley, and Havenner and Swamy, the first-order variant of the generalized ARIMA stochastic coefficient regression method has the following form:

(1) $$Y_t = X_t'\beta_t$$

(2) $$\beta_t - \bar{\beta} = \psi(\beta_{t-1} - \bar{\beta}) + a_t,$$

where Y_t is the dependent variable, X_t' is a vector of explanatory variables including a unit element for the intercept term. The stochastic coefficient vector (B_t) is assumed to follow a first-order vector autoregressive process with mean vector $\bar{\beta}$. The error term a_t is assumed to be a sequence of uncorrelated vector random variables with expected mean value of zero and constant variance-covariance matrix denoted by Σ_a. The correlation matrix (ψ) is a $K \times K$ matrix of fixed but unknown correlation parameters. Because Σ_a and ψ are not known but must be estimated, the SWAMSLEY (Swamy and Tinsley) computer program provides for a data-based iteration estimation procedure in which ψ and Σ_a are initially arbitrarily chosen. Through several iterations, efficient and consistent estimates of ψ, Σ_a and β_t are derived. The mean value of the stochastic coefficients from the iteration with the lowest root mean square error is then selected.

Argentine Agricultural Policy in a Multiple-Input, Multiple-Output Framework

Lilyan E. Fulginiti and Richard K. Perrin

This study shows that government interventions in Argentine agriculture substantially reduced the growth rate of output 1940–80. A multiple product, multiple input, aggregate translog profit function is estimated. Supply elasticity estimates range from zero for linseed to 1.6 for sorghum. Estimates of intervention wedges together with the estimated structure imply that export taxes, import restrictions, and domestic taxes each in isolation could have reduced aggregate output by as much as 25%–30%. These and other interventions increased beef as a share of outputs and increased the cost shares of purchased inputs and labor at the expense of capital inputs.

Key words: agricultural production, agricultural structure, Argentina.

Argentine agricultural output grew at a rate of about 1.4% per year between 1940 and 1972 (Cavallo and Mundlak, p. 13), which is a very sluggish growth rate, given earlier rates of 1.8% for 1908–20 and 2.2%, 1920–40 (Schultz). It also is sluggish relative to growth in U.S. agricultural output of 1.9% during the same period. Adjusting for factor use, total factor productivity in Argentine agriculture grew at a rate of only 0.6% during this period, compared to 1.2% in the rest of the Argentine economy (Cavallo and Mundlak) and compared to about 1.9% in U.S. agriculture (USDA).

A number of hypotheses have been offered to explain this sluggish growth, including heavy taxation of the agricultural sector, slow technological advance, and a lack of profit motivation among the dominant large landowner class. Empirical studies by Cavallo and Mundlak, Gluck, and Reca (1974) indicate that various price and tax policies have indeed significantly affected agricultural output. The purpose of the study reported here is to provide further evidence on this issue by simultaneously considering the effect of a number of such price and tax policies on the production of seven agricultural commodities and the use of three agricultural inputs in Argentina.

The approach of the study is first to specify and estimate a multiple-input, multiple-output model of the Argentine agricultural sector, based on 1940–80 time-series data. This model is developed using applied duality theory in a manner similar to previous studies of aggregate agricultural technology by Antle; Ball (1988); Shumway; Shumway, Saez, and Gottret; and Weaver. The resulting estimates of elasticities are then used to examine the effects of price and tax policies in a comparative static framework.

The Economic Model

The producer's variable profit function may be defined as

$$(1)\quad \pi(p, r; z) \equiv \max_{xy}\{p\,y - r\,x;\ (y, x; z) \in T\},$$

where p is a vector of m output prices; r is a vector of n input prices; y is a vector of m output quantities; x is a vector of n input quantities; z is a vector of l fixed factors; and T is a closed, bounded, smooth, and strictly convex set of all feasible combinations of inputs and outputs, i.e., a production possibility set. In addition, the technology is assumed to exhibit constant returns to scale. The profit function as defined by

Lilyan Fulginiti and Richard K. Perrin are an assistant professor at Iowa State University and a professor at North Carolina State University, respectively.

With the usual disclaimers, the authors are grateful for comments and assistance provided by Antonio Besil, Domingo Cavallo, John Dutton, Paul Johnson, A. R. Gallant, Luis Pellegrino, M. K. Wohlgenant, and two anonymous *Journal* reviewers.

(1) is assumed to be convex, linearly homogenous, and monotonic in prices. If, in addition, the variable profit function is twice continuously differentiable with respect to prices, applying Hotelling's lemma yields the system of continuously differentiable output supply and input demand functions:

$$(2)\quad \frac{\delta\pi}{\delta p_i}(p, r; z) = y_i^*(p, r; z)\ i = 1, \ldots, m$$
$$\frac{\delta\pi}{\delta r_h}(p, r; z) = -x_h^*(p, r; z)\ h = 1, \ldots, n,$$

where y_i^* and x_h^* are profit-maximizing amounts of output i and input h given prices and fixed inputs.

For this study of Argentine agriculture, a translog specification is used which, as is well known, is a flexible functional form in that it provides a local second-order approximation to any arbitrary functional form.

In general,

$$(3)\quad \tilde{\pi} = \alpha_0 + \alpha\,\tilde{d} + \frac{1}{2}\tilde{d}'\,\beta\,\tilde{d},$$

where

$$\tilde{\pi} = \ln \pi$$
$$\tilde{d} = \begin{bmatrix} \tilde{p} \\ \tilde{r} \\ \tilde{z} \end{bmatrix} = \begin{bmatrix} \ln p \\ \ln r \\ \ln z \end{bmatrix}.$$

First-order differentiation of this profit function yields a system of share equations:

$$(4)\quad M = \alpha + \beta\tilde{d},$$

where M is a column vector consisting of output shares and the negative of input shares, α is a vector, and β is a matrix of the coefficients in equation (4).

Second-order differentiation of the profit function, with some manipulation of the results, yields response elasticities [see Weaver's equation (19) for elasticities as functions of estimated parameters and estimated shares]. In the multiple-input, multiple-output case, the signs of these elasticities are not an indication of isoquant curvature because all other quantities are adjusting optimally to the price change as well.

The Hicksian measure of biases induced by technical change is used in this analysis. It is based upon marginal rates of substitution and must be measured between input pairs. Technological change is said to be Hicks x_h-saving, or x_h-neutral or x_h-using relative to x_k if

$$(5)\quad B_{hk} = \delta\left(\ln\frac{x_k^*}{x_h^*}\right) \Big/ \delta\tilde{z}\gamma \gtreqless 0,$$

where the variable $Z\gamma$ is arbitrarily designated as an index of technological change (Lau). A consistent estimator for this bias in the impact of technical change for the translog specification can be derived as

$$(6)\quad \hat{B}_{hk} = \frac{\hat{\beta}_{k\tilde{z}\gamma}}{M_k} - \frac{\hat{\beta}_{h\tilde{z}\gamma}}{M_h}.$$

Argentine Agricultural Sector Data

Parameters of the agricultural supply and factor demand structure for Argentina are estimated using the functional form described previously, with time-series data for the years 1940–80. The seven aggregate output categories examined are wheat, corn, grain sorghum, sunflower, linseed, soybeans, and beef. The three variable input categories are labor, capital, and an aggregate of fertilizers, seeds, and chemicals. Land and precipitation are considered fixed within the annual observation interval. A third fixed input variable is time in years, which represents the index of technological change. This is equivalent to specifying exponential rates of output- and input-augmenting technological change. The trend variable could be a poor proxy for technical change if the change does not occur at a constant annual rate.

The seven commodities constitute over 70% of the value of all agricultural output in Argentina when industrial commodities such as sugar, cotton, and tobacco are included, along with fruits and vegetables. However, capital share is available only for the entire agricultural sector, and the land index is a quality-adjusted index which was available only for the entire sector. Any bias introduced by these approximations is probably small because of the consistently large fraction of total agricultural resources devoted to this set of commodities. The six crops used 94% of harvested crop acreage in the first five years of the data and 89% in the last five years, while beef used about six times the amount of land devoted to crops during most of this period.

Crop production data, in millions of metric tons, were obtained from Banco de Analisis y Computacion. Average crop prices received by farmers were obtained from Bolsa de Cereales, and were converted to 1960 pesos per quintal. Beef data, cash receipts, and farm price in pesos

per kilogram, were obtained from Argentina Junta Nacional de Carnes and were also deflated to 1960 pesos, as are all other prices in the study.

Labor data consist of the number of workers in the agricultural labor force, and the average annual agricultural wage earnings including perquisites, taken from Cavallo and Mundlak (tables 25 and 26, extended to 1980 in a personal communication from Cavallo).

Expenditure on capital services is an aggregate of several categories: repairs and operation of motor vehicles and machinery, machine hire and custom work, electricity, interest on nonreal estate debt, and depreciation on motor vehicles, machinery, and equipment. These expenditure data were taken from unpublished sources at the Ministry of Agriculture (SAG) and deflated. For the price of capital services, the procedure of Cavallo and Mundlak was used to calculate the real rate of return on capital in agriculture (though our numbers differ from theirs because of different aggregates of inputs and outputs). This rate is calculated as the ratio of the value of production (net of the values of labor and "other" inputs) to the value of agricultural capital including land. (Conceptually, this is similar to Ball's 1985 measure of the rate of return but without his deduction of depreciation, capital gains, and property tax from the value of production. The Cavallo-Mundlak procedure thus overestimates the Ball rate of return by an amount that would be nearly constant from year to year.) The rate of return we calculate averages .091, ranging from a low of .042 in 1949 to a high of .148 in 1973.

Expenditures on fertilizers, chemicals, and seeds for each of the six crops were available from SAG, though not in published form. These were aggregated across crops and inputs and deflated to provide the expenditure series for "other" inputs. A Tornquist-Theil price index for fertilizers, seeds, and chemicals was constructed using unpublished SAG price data for these inputs.

The land variable is a quality-adjusted index, calculated from Cavallo-Mundlak data (updated in private communication) as follows. The current value of agricultural land is taken as the difference between the capital stock in agriculture with land included and the capital stock with land excluded. This value is divided by a price index for land which consists of the Cavallo and Mundlak land price series. Precipitation, the second fixed input, was measured as millimeters per year for a number of weather stations in the Pampas.

Estimation and Results

A stochastic structure must be assumed for the equation system (4) in order to estimate the parameters of the profit function. We assume that any deviations of the observed output supply and input demand quantities from their profit-maximizing levels are caused by random errors in optimization, and that these disturbances are additive with zero means and positive semidefinite variance-covariance matrix. This stochastic version of the share equations (4) is estimated using the seemingly unrelated regression technique of Zellner. The system was estimated with the linseed share eliminated; those coefficients are identifiable from the other parameters using the restrictions shown in table 1. The system was estimated with a single iteration because for the iterative method the likelihood function tends to be unstable with a large numbers of parameters as occurs here.[1] In addition, the absence of normality in the errors of the share equations favors the least-squares SUR approach as opposed to the maximum likelihood iterative SUR approach.

The equations were restricted to satisfy the symmetry and homogeneity conditions as shown in table 1. Table 2 presents the parameter esti-

[1] Personal communications from A. R. Gallant; see also Deaton. Their argument is as follows. With many equations and many parameters in the system to be estimated, the first-iteration parameter estimates are likely to fit one of the equations nearly perfectly. Successive iterations will quickly drive the variance-covariance matrix toward singularity, and the likelihood function turns unstable as the determinant of this matrix approaches infinity.

Table 1. Symmetry and Homogeneity Conditions Imposed

Symmetry	$\beta_{ij} = \beta_{ji};\quad \forall i,j$
	$\beta_{hk} = \beta_{kh};\quad \forall h,k$
	$\beta_{lk} = \beta_{kl};\quad \forall l,k$
Homogeneity in prices	$\sum_{i=1}^{m} \alpha_i + \sum_{k=1}^{n} \alpha_k = 1$
	$\sum_{j=1}^{m} \beta_{ij} + \sum_{k=1}^{n} \beta_{ik} = 0;\quad \forall i = 1, \ldots, m$
	$\sum_{j=1}^{m} \beta_{hj} + \sum_{k=1}^{n} \beta_{hk} = 0;\quad \forall h = 1, \ldots, n$
	$\sum_{j=1}^{m} \beta_{rj} + \sum_{k=1}^{n} \beta_{rk} = 0;\quad \forall r = 1, \ldots, l$
Homogeneity in fixed inputs	$\sum_{r=1}^{l} \beta_{ir} = 0;\quad \forall i = 1, \ldots, m$
	$\sum_{r=1}^{l} \beta_{hr} = 0;\quad \forall h = 1, \ldots, n$

[a] Standard errors in parentheses.

mates of the restricted model. The table contains a total of ninety-five parameters, twenty of which are significant at the 1% level, twenty-six at the 5% level, and thirty-one at the 10% level. Eight of the ten own-price coefficients are significant at the 1% level. Durbin-Watson statistics for the restricted SUR equations ranged from 1.08 to 2.25, within the 5% levels of significance for forty-one observations and thirteen regressors.

In addition to the imposed properties of symmetry and homogeneity, monotonicity and convexity are additional properties of a profit function that cannot be satisfied globally with the translog function. However, they may hold at the specific data points used in estimating the function. Monotonicity is violated if predicted output shares are negative or predicted input shares are positive. For the restricted SUR estimates, monotonicity is satisfied at the average of the data points, and at 387 of the 410 data points (18 of the 23 negative share predictions occur at data points where the observed data share is zero or less than 0.01). Convexity is violated if own-price elasticities have the wrong sign. This condition is violated by the linseed elasticity of −.08 at the average of the data points, and it is violated at 32 of the 410 data points (19 of which are linseed elasticities).

While the structure of equation (4), as shown in table 2, can be used to evaluate the effects of prices and fixed factors on the mix (shares) of outputs and inputs, elasticities must be derived to evaluate the effects on the levels of outputs and inputs. The elasticities can be obtained by differentiation of the share equations [see Weaver's 1983 equation (19) for elasticities as functions of estimated parameters and estimated shares]. Table 3 shows own-price and cross-price elasticities calculated in this manner from the table 2 parameter estimates, evaluated at the mean value of shares.

Own-price supply elasticities are between 0.7 and 1.5 except for linseed, which is slightly negative. These elasticities are larger than the 0.1–1.1 levels estimated by Weaver, by Ball, and by Shumway, Saez, and Gottret for similar commodities within the United States using similar methods. Of the twenty-one cross-supply elasticities, fifteen are positive indicating complementary relationships among the commodities. (Ball, Weaver and Antle and Aitah found all cross relationships to be complementary in their studies.) In other words, as the price for a commodity rises, new inputs are drawn into general production (note the input elasticities in response to product prices), causing an increase in the production of other products as well. Given the elasticities in table 3, the elasticity of beef supply in response to a general increase in all output prices is 1.41, compared with 1.42 for wheat; 1.49 for corn; 2.06 for sunflowers; and 0.8, 4.58, and 1.42 for linseed, soybeans, and sorghum, respectively. A general rise in product prices then, if not offset by higher input prices, would induce a relatively elastic response of aggregate output, but it would not affect all commodities equally.

Own-price input demand elasticities for capital, labor, and others are −1.94, −1.03, and −.97, respectively, again indicating a substantial degree of price responsiveness by Argentine producers. These levels are in the same range as those estimated by Ball, by Weaver, and by Antle and Aitah (all of whom used the translog), but are much higher than the −.08 to −.28 range estimated by Shumway, Saez, and Gottret, who used the normalized quadratic. The latter study showed all input cross elasticities to be positive, while the other three studies as well as this one

Table 3. Estimated Own- and Cross-Price Elasticities

Quantity of:	Price of Beef	Wheat	Corn	Sunflower	Linseed	Soybean	Sorghum	Capital	Labor	Others
Beef	1.17	0.10	0.08	0.03	0.02	0.02	−0.02	−0.95	−0.26	−0.20

Corn	0.22	−0.29	1.48	−0.11	0.02	0.04	0.12	−0.82	−0.48	−0.19
Sunflower	0.22	0.58	−0.33	1.10	0.38	−0.03	0.14	−1.67	−0.23	−0.17
Linseed	0.27	−0.26	0.08	0.49	−0.08	0.15	0.16	−0.62	0.08	−0.27
Soybean	0.78	1.75	0.57	−0.14	0.54	0.66	0.42	−2.96	−0.78	−0.85
Sorghum	−0.19	−1.03	0.55	0.21	0.18	0.13	1.56	−1.11	−0.44	0.14
Capital	1.08	0.65	0.34	0.23	0.07	0.09	0.10	−1.94	−0.49	−0.13
Labor	0.63	0.89	0.43	0.07	−0.02	0.05	0.09	−1.03	−1.03	−0.07
Others	0.83	0.21	0.29	0.08	0.10	0.09	−0.05	−0.48	−0.12	−0.97

show all of them to be negative, i.e., show inputs to be gross complements. It is useful to note the elasticity of response of a single input to a general increase in all input prices: −2.55 for capital, −2.13 for labor, and −1.56 for others. A general rise in input prices, with output prices constant, would thus tend to reduce the use of capital and labor much more than other inputs.

Finally, output elasticities with respect to input prices are in general negative. The sizes of these elasticities suggest that policies affecting credit and wages will have noticeable effects on output levels as well as input use. Further, the size of input elasticities with respect to beef, wheat, and corn prices suggests that input useage is responsive to output prices and policies that affect output prices.

The effect of technical change on relative levels of input use (bias) is revealed by comparing the time trend coefficients of each input share equation after dividing it by that input share [the terms in equation (6) above]. The estimates of these adjusted share trends (using average values of shares) are −.264 for capital, −.257 for labor, and .078 for others. Thus, technical change was biased most strongly in favor of "other" inputs and most strongly against capital. Expressed in traditional terms of pair-wise biases [equation (6)], the technical change was labor saving relative to others (.335) and capital saving relative to both labor (.007) and others (.342). This ordering of biases is consistent with the induced innovations hypothesis. Average annual price increases between the first and last five-year periods of the data were 6.8% for capital, 1.1% for labor, and 0.7% for others.

Implications for the Effects of Policies

Relative stagnation of Argentine agriculture may in part result from policies that have raised the producer price of inputs and lowered the producer price of most outputs. In this section we examine the implications of the model for evaluating the impact of various government policies on the mix of outputs and inputs and on levels of production in Argentine agriculture. The relevant policies and their approximate price effects are identified first, and then the estimated coefficients are utilized to estimate their impacts.

Estimated Price Effects

In general, the effect of a policy can be described as a percentage price wedge, that is, the difference between the demand price and the supply price, expressed as a percent of the equilibrium price. We make the assumption in this study that prices are indeed exogenous to the agricultural sector. (Argentina is a small country in the world market for these commodities, and, because agriculture represents but 7%–10% of gross national product (GNP), that sector is a reasonably small user of capital, labor, and "other" inputs.) Therefore, the price wedges created by various policies can be characterized as exogenous price changes for both inputs and outputs. We consider five kinds of policies which have affected prices paid or received by farmers: export taxes, import restrictions, exchange rate controls, domestic taxes, and minimum wages.

Ad valorem export taxes on crop and livestock products have been persistent and significant over the past forty years. Cavallo and Mundlak (pp. 59–60) report an effective average export tax rate of 29% on the entire agricultural sector from 1940 through 1972. Mielke (p. 6, p. 19) reports rates for particular commodities between 1958 and 1982. Based on data reported in these sources, we estimate conservatively that ad valorem export taxes resulted in average wedges of the following sizes: 10% for beef, 15% for soybeans, and 25% for the other crops (table 4).

Imports of machinery, chemicals, and fertilizers have been restricted both by tariff and nontariff barriers, and the restrictions have not been uniformly applied. Therefore, any estimate of the average price wedge imposed must be somewhat arbitrary. We accept Cavallo and Mundlak's estimate (p. 156) that the average tariff was 37%. With infinite elasticity of supply, prices of imported goods would fall by $(1-1/1.37) =$ 26% from actual levels if the tariffs were eliminated. This is a more conservative estimate of the price wedge than suggested by Mielke (who indicates, pp. 6–7, that tariffs alone during much of this period were 60% on machinery, seeds, and fertilizer), or by Sturzenegger (whose estimates, p. 225, of the implicit tariff coefficient for 1960–80 average 1.76).

Reca (1980) and Mielke both cite a World Bank study which estimated that overvaluation of the peso averaged 38% during 1968–74. Cavallo and Mundlak assert that 20% overvaluation is a reasonable estimate for the 1939–73 period. But the more recent World Bank study by Sturzenegger puts the figure at 18% for 1960–80; this estimate is utilized in this study.

Domestic taxes considered here include the value-added tax and social security taxes on la-

Table 4. Estimated Farm Price Changes Due to Elimination of Policies

Commodity	Export Taxes	Import Restrictions	Overvalued Currency	Domestic Taxes	Minimum Wages
	Policy Set				
	(price change in %)				
Beef	10	0	18	0	0
Wheat	25	0	18	0	0
Corn	25	0	18	0	0
Sunflower	25	0	18	0	0
Linseed	25	0	18	0	0
Soybean	15	0	18	0	0
Sorghum	25	0	18	0	0
Capital	0	−26	18	−18	0
Labor	0	0	0	−13	−10
Others	0	−26	18	−18	0

bor. The value-added tax has been 18% since it was introduced in the late 1970s to replace a number of other business taxes. Because no estimates of these other taxes are available, we assume that they, too, produced an average wedge of 18% on capital and "others" in prior years. Social Security taxes have been about 40% of wages in recent years (Reca 1980, p. 13, Sturzenegger, p. 36). These taxes do not apply to producers and nonsalaried family workers, however, who constituted two-thirds of the farm labor force in 1969 (Banco de Analisis y Computacion). We estimate that their average net effect has been to insert a 13% wedge in farm labor market (one-third of the current level of the tax). Following Reca, we estimate that minimum wages have inserted a 10% wedge in the farm labor market.

Other policies which might have introduced input and output wedges are official support prices and land taxation. After considering discussions of these policies by Reca and Mielke, it is doubtful that these policies have had significant effects on these markets over the forty-year span of our data. Agricultural credit subsidies may have been important, but there is little data on which to evaluate the price-wedge equivalent impact of these policies; thus, they are excluded from the analysis. It is clear that elimination of the policies we do consider would increase output prices and decrease input prices, with grains affected more than beef (beef producers apparently have been more successful than other producers in keeping export taxes low).

Predicted Share Effects of Policies

To evaluate the effect of policy wedges on shares of inputs and outputs, we use equation (4) with the coefficients of table 2 as estimates of coefficients α and β. The change in the share vector M equals β times the change in d, with the wedge effects in table 5 being the changes in d. The predicted changes in profit shares resulting from elimination of wedges are reported in table 5. Because the profit share changes are difficult to interpret, these results also are presented in terms of revenue and cost share changes (table 6). Grains other than linseed would increase their share of output at the expense of beef. Capital would increase its share of inputs at the expense of labor and other inputs. This latter effect occurs, even though price reductions are about the same for the three inputs because of the relatively greater elasticity of capital and labor in response to all input prices as noted above.

Predicted Quantity Effects of Policies

To predict the effects on the levels of inputs and outputs, we use a simple linear elasticity model similar to (4):

$$(7) \qquad \begin{bmatrix} \delta \ln y \\ \delta \ln x \end{bmatrix} = \Sigma \begin{bmatrix} \delta \ln p \\ \delta \ln r \end{bmatrix},$$

where Σ is the 10×10 matrix of price elasticities from table 3, and the $\delta \ln p$ and $\delta \ln r$ are again the percentage price changes shown in table 4.

Two caveats are in order regarding the use of this linear elasticity model. First, the model assumes that both output and input prices are fixed. Thus, it overestimates quantity responses that would occur if output prices were to fall or input prices were to rise with expansion. Second, equation (7) is a linear approximation at a given point in price-quantity space. As such it over-

estimates the quantity effect of price rises compared to curvilinear supply and demand functions. Despite these limitations, the linear elasticity model is useful in evaluating the relative magnitudes of the effects of various policies.

Trade-related policies (export taxes, import restrictions and currency overvaluation) have been by far the most important distortions affecting agricultural prices (table 4). Elimination of export taxes alone would have increased production from as little as about 15% for beef and linseed to 30% for wheat and corn and nearly 100% for the relatively minor crop of soybeans (table 7). The share-weighted average increase in production would be 27%. Elimination of import restrictions would have about the same overall effect on output (29%) but would have a larger impact on beef. The output effects of exchange rate devaluation would be more modest, ranging from no effect to an increase of 14% for soybeans, with a share-weighted average of 7%.

These estimates tend to corroborate the findings of the Cavallo-Mundlak study, which indicated that the combination of trade liberalization and exchange rate management would have produced increases of 30%–40% in per capita agricultural output over a twenty-year period. We find in addition that eliminating the value-added tax, social security tax, and other input taxes would increase average output by 25%, approximately the same level as for export taxes and import restrictions, with this effect being fairly uniform across commodities. Finally, the impact of eliminating minimum wages in agriculture would increase average output by only 4%.

Table 7. Estimated Quantity Changes from Elimination of Policies

	Policy Set[a]				
Commodity	Export Taxes	Import Restrictions	Overvalued Currency	Domestic Taxes	Minimum Wages
	(quantity change in %)

Others	26	38	2	28	1
Weighted input	43	44	10	38	6

[a] Predicted from equation (7) and the price changes in table 5 with variables at sample mean.

These increases in outputs are of course created by additional input use as shown in table 7. The ratio of weighted output change to weighted input change is 0.64 for each of the policy effects, a measure of the elasticity of production from variable inputs.

It is tempting to sum the effects of eliminating the various policies, which is technically correct given the linear elasticity model. However, the linear approximation errors referred to earlier would become so significant in the case of such large equilibrium displacements that little confidence could be placed on the quantitative results. The most that can be prudently concluded from this analysis is that the major policies affecting agricultural output are export taxes, import restrictions and domestic taxes, and that any one of these alone could have restricted average output by as much as 25%.

Conclusions

This study examines Argentine agriculture to determine the possible impact of price-related policies in contributing to the relatively slow rate of growth of agricultural output since 1940. The study estimates a system of seven commodity supply and three input demand equations with a translog profit function specification. The profit function approach was satisfactory with regard to statistical significance and a priori plausibility of coefficients, although it satisfied neither monotonicity nor convexity properties over the entire data set. Estimated supply elasticities were 1.2 for beef, 1.4 for wheat, 1.5 for corn, and 0 to 1.6 for the minor crops. Estimated demand elasticities were -1.9 for capital and -1.0 for both labor and "other" inputs.

The responsiveness of both variable outputs and variable inputs to prices indicates that policies affecting price can have important quantitative effects. The major sets of such policies in Argentina in terms of price effects have been export taxes at 25% (10% for beef), import restrictions at 26% for capital and "other" inputs, currency overvaluation at 18% on tradable items, minimum wages at 10%, and other domestic taxes at 15%. Using the estimated elasticities from our model in a linear elasticity comparative statics framework, the aggregate (share-weighted) output effects of eliminating these sets of policies are 27% for export taxes, 29% for import restrictions, 7% for currency overvaluation, 25% for domestic taxes, and 4% for minimum wages. The approximation errors inherent in the linear model may lead to substantial overestimates at these levels of equilibrium displacement, but the results seem to corroborate the Cavallo and Mundlak conclusion that combined trade and exchange rate policies affected output by 30%–40% over a twenty-year period. In addition, the results show that the combined policies increased the share of beef in output by eleven percentage points, at the expense of crops (other than linseed), and decreased the input share of capital by 13% in favor primarily of nonlabor variable inputs.

If export taxes, import restrictions or domestic taxes had been eliminated between the first and last decades of our study, the resulting 25%–30% increase in production would have translated to an increased annual growth rate from 1.4% to 2.2% per year over the thirty-year interval. Such a growth rate would have been comparable to earlier levels in Argentine agriculture and would have exceeded the rate of growth in U.S. agriculture during the same period. Thus, we conclude that the price effects of various sets of policies in Argentina were sufficient to explain the relatively slow rate of growth of agricultural output.

European Community Enlargement: Impact on U.S. Corn and Soybean Exports

Tassos Haniotis

This paper utilizes the framework of an Armington model to analyze the impact of the European Community enlargement on U.S. corn and soybean exports. Results indicate that the enlargement has a significant and negative impact on U.S. corn exports to the new EC members. Increases in U.S. soybean exports are much smaller in volume terms. Declines in U.S. corn export prices outweigh the insignificant increases in U.S. soybean export prices and therefore accentuate U.S. losses. However, the U.S.–EC agreement on their enlargement dispute cut net losses of U.S. corn and soybean exports to Spain and Portugal by about a third.

Key words: Armington model, EC enlargement, U.S. farm exports.

The 1986 enlargement of the European Community (EC) to include Spain and Portugal was a positive step toward the ideal of European unity; however, it is not necessarily in harmony with U.S. agricultural interests. With declining U.S. farm exports in the 1980s, the EC enlargement complicated the already strained U.S.–EC agricultural trade relations stemming from the adverse impact of the Common Agricultural Policy (CAP) on EC imports and world markets. The enlargement brought the two sides to the brink of a trade war and, despite the agreement on compensation for U.S. losses of grain exports to Spain, the underlying causes of U.S.–EC trade conflicts are still unresolved.[1] Consequently, the future of the agricultural trade relations between the United States and the EC is surrounded by uncertainty, which is further compounded by the process of CAP reform and its interaction with the new U.S. farm policy objectives outlined in the 1985 Food Security Act (FSA).

The enlarged EC is an important market for U.S. agricultural exports because it absorbed one quarter of total U.S. agricultural exports in 1986. Two products, corn and soybeans, accounted for 78% of U.S. farm exports to the Iberian peninsula and 28% of U.S. exports to EC-10 (USDA, *Foreign Agricultural Trade*). Moreover, 45% of total U.S. soybean exports are destined to the enlarged EC. Hence, assessing the impact of the enlargement on U.S. corn and soybean exports is important both in terms of changes that were generated in trade flows to the region and in terms of the enlargement impact on U.S.–EC agricultural trade relations. Furthermore, the EC markets for corn and soybeans exemplify two extreme cases in agricultural trade—complete protection of, and free access to, a domestic market. Because of this combination, which has created significant imbalances in EC import patterns (Buchholz, Commission of the European Communities), tariff changes in corn and soybeans exported to Spain and Portugal were implemented in opposite directions. Corn exports to the region fell under the EC variable import levy regime, thus resulting in significantly higher import tariffs. On the other hand, the moderate import tariffs on soybeans were abolished be-

The author wishes to acknowledge constructive comments and suggestions by Glenn Ames, Jack Houston, William H. Meyers, Fred White, and two *Journal* reviewers on earlier drafts of this paper.

[1] On 30 Jan. 1987, the U.S. and the EC settled their enlargement dispute by agreeing on a quota of low-tariff corn and sorghum imports into Spain and Portugal from non-EC suppliers (2,000 and 400,000 MT, respectively), waiving the requirement that Portugal reserve 15% of its grain market for other EC members, and reducing EC custom duties on some industrial and processed agricultural products.

cause of the zero tariff binding for EC oilseed imports.[2]

The objective of this article is to analyze the impact of the EC enlargement on U.S. exports of corn and soybeans. The model is specified in the next section, while data and the empirical estimation of the model are subsequently explained. The impact of the enlargement is then assessed by model simulations. Concluding comments are presented in the last section.

The Model

The framework of a model for differentiated products, first developed by Armington, is utilized in this study. Denote, henceforth, commodities that are differentiated by kind as "goods" (e.g., soybeans vs. corn), and goods that are differentiated by origin as "products" (e.g., Brazilian soybeans vs. U.S. soybeans). Further assume: (*a*) weak separability of the (linearly homogenous) utility function, (*b*) constant elasticity of substitution between any two products of a good in a given market, and (*c*) equality of the elasticity of substitution between any pair of products in a given market.

Then, an importing region's purchasing decision process can be treated as a two-stage process. In the first stage, expenditure allocation among n imported goods is determined by maximizing importers' utility subject to their income constraint, with resulting import demand functions of the form $X_h = X_h(P_1, P_2, \ldots, P_n, Y)$, where X_h and P_h are quantity and price indexes for good h and Y is income. In the second stage, total expenditure on each good (Y_h) is allocated among the m products of that good. This allocation is a solution to the problem of minimizing the cost of purchasing good h, with resulting import demand functions of the form $X_{hi} = X_{hi}(P_{h1}, P_{h2}, \ldots, P_{hm}, Y_h)$. Minimizing the cost of procuring the quantity index X_{hk} subject to X_h and solving for the first-order conditions yields the following import demand function, expressed in share form, for product X_{ik} imported from region i into region k (Armington, Sarris 1980):

$$(1) \qquad X_{ik}/X_k = a_{ik}^{\sigma_k}(P_{ik}/P_k)^{-\sigma_k},$$

where the subscript h of the good is dropped for notational simplicity, a_{ik} is a constant that can be interpreted as the share of the kth exporter in the ith market, σ_k is the absolute value of the elasticity of substitution between imports from different origins in region k, P_{ik} is the price of X_{ik}, and P_k is the price index over i products of X_k in region k.

In the most general form, percentage changes in the demand for X_{ik} are given by

$$(2) \qquad \tilde{X}_{ik} = \Theta_k\tilde{Y}_k + \varepsilon_{iik}\tilde{P}_{ik} + \sum_{\substack{j=1\\ j\neq i}}^{m} \varepsilon_{jik}\tilde{P}_{jk} + \sum_{\substack{g=1\\ g\neq h}}^{n} e_{gh}\tilde{P}_g,$$

where ε_{jik} is found as (Alston and Scobie):

$$(3a) \qquad \varepsilon_{ijk} = -(1 - S_{ik})\sigma_k + S_{ik}\varepsilon_k,$$

$$(3b) \qquad \varepsilon_{jik} = S_{jk}(\sigma_k + \varepsilon_k).$$

Equation (2) expresses the demand side of the model used in the present analysis. Tildes ($\tilde{\ }$) denote percentage changes ($\tilde{x} = dx/x_0$), Y_k represents total income in region k, P_g is the price of related good g in region k, and S_{ik} is the value share of imports of the product exported from region i to region k. Parameters σ_k, ε_k and Θ_k are, respectively, the elasticity of substitution, the import demand elasticity, and the income elasticity for good h, and subscript j corresponds to products of the imported good competing with product i in region k. Finally, e_{gh} is the cross-price elasticity of good h with respect to good g in region k.

Following Sarris (1983), it is assumed that export supply flows of the ith exporting region, in terms of percentage changes, are given by

$$(4) \qquad \tilde{X}_i = \beta_i\tilde{p}_i + \Phi_i\Delta t,$$

where p_i is the internal export price (excluding all export subsidies or taxes), β_i is the export supply elasticity, and Φ_i is a trend constant.

Import prices are linked to export prices by identities that have the following form:

$$(5) \qquad \tilde{P}_{ik} = E_{ik}\tilde{p}_i r_{ik} + \tilde{\tau}_{ik},$$

where E_{ik} is the price transmission elasticity, r_{ik} is the exchange rate between currencies of regions i and k, and τ_{ik} is an exogenous shifter through which changes in policy variables, such as tariff changes, can be introduced into the model. Finally, the model is closed by the following clearing condition that restricts export

[2] The Dillon round of GATT negotiations (1960–61) resulted in the zero tariff binding for oilseeds, oilseed products, and certain nongrain feedstuffs imported into the EC (Hathaway).

supply from region i to equal the summation, across all regions k, of import demand from region i:

$$(6) \qquad 0 = \tilde{X}_i - \sum_{k=1}^{m} H_{ik}\tilde{X}_{ik}.$$

H_{ik} is the base period quantity share of exports from the ith exporting region to the kth market. Equations (2), (4), (5), and (6) form a system of N equations, where $N = 2m^2 + 2m$. The system yields percentage changes in its endogenous variables that result from exogenous variable changes. Trade policy changes and their impact on trade flows can be evaluated by varying the value of the $\bar{\tau}_{ik}$ parameters, while different assumptions concerning the exogenously determined variables ($\tilde{Y}_k$, Φ_i) could shed light into their importance in determining trade flows.

Data and Empirical Estimation

Because this analysis focuses on U.S. exports into the EC and its new members, the world is divided into five regions: the United States, (US); the European Community-10 (EC); Spain and Portugal (SP); other major exporters (OE)—Argentina, South Africa, and Thailand for corn, Brazil and Argentina for soybeans; and the residual Rest of the World (RW). Data were obtained from the European Community *Analytical Tables of Foreign Trade*, the United Nations *Commodity Trade Statistics*, and USDA supply utilization tables. Prices are per unit values, in real terms.[3] In order to adjust all prices for exchange rate fluctuations, effective consumer price indexes were constructed from data of the *International Financial Statistics* of the International Monetary Fund. Average trade shares (S_{ik}, H_{ik}) for corn and soybeans, in volume terms for exports and value terms for imports, were computed from trade flow matrices constructed for the 1983–85 period (Haniotis). This period was selected as representative for pre-enlargement trade flows into Spain and Portugal.

First-stage import demand equations were estimated using time-series annual data for the 1966–85 period and were specified as

$$(7) \qquad \ln M = b_0 + b_1 \ln PC + b_2 \ln PS + b_3 \ln Y + b_4 \ln S + b_5 T + b_6 D,$$

where M is the quantity of imports for soybeans or corn; PC and PS are import prices of corn and soybeans, respectively; Y and S represent real income and domestic supply in the importing region; T is time, and D is a dummy variable for the period after the first EC enlargement.[4] Because of the log-linear form of the import demand equations, estimated coefficients are the elasticities of the corresponding variables.

Results of the estimated first-stage import demand equations for EC, SP, and RW are reported in tables 1 and 2. Import demand for corn is inelastic in all three importing regions, while the soybean import demand elasticity exceeds unity only in SP. Own-price elasticities of import demand were statistically significant at the .05 level or higher in five of the six estimated equations (the exception being the RW corn import elasticity). Income elasticities were generally higher than one and statistically significant in all cases. On the other hand, cross-price elasticities were characterized by low values and high standard errors in all cases. Signs of all estimated parameters were as expected.[5]

The elasticities of substitution, σ_k, were estimated from equation (1) by transforming it into a logarithmic form and then pooling cross-section, time-series data of exports from all origins into an importing region (Figueroa). Since the assumption of product differentiation implies that the elasticity of substitution should not be constant among all pairs of products within a market, it has been suggested that the CRESH (constant-ratio elasticity of substitution and homothetic) function (Hanoch) is more consistent than the CES (constant elasticity of substitution) function in a differentiated products model (Deppler, Lopez). In this study, however, the use of the CES function appears appropriate because the selection of exporting regions is based on the fact that, for the period for which estimates σ_k were obtained (1974–85), corn and soybean exports to EC and SP were originating mainly from two regions, the US and OE, and a single pair of products within a market was relevant.

Estimated second-stage import demand equa-

[3] Exceptions are the EC threshold price for corn, which was adjusted on a calendar year basis and used as the import price in the estimated EC import demand equation for corn, and the U.S. export prices for corn and soybeans (FOB Gulf ports), which were used in the estimation of the corresponding U.S. export supply elasticities.

[4] The price of soybean oil (PSO) was included in the estimated equation for EC soybean imports.

[5] Alternative specifications of the first-stage import demand equations, attempting to explore cross-price effects with other products, did not yield satisfactory results.

Table 1. Estimated Import Demand Equations for Corn

First-Stage

EC: $$\ln MC = \underset{(7.939)}{4.971} - \underset{(0.421)}{0.804\ln PC} + \underset{(0.110)}{0.160\ln PS} - \underset{(0.313)}{0.478\ln DS} + \underset{(1.619)}{2.802\ln Y} + \underset{(0.161)}{0.367D} - \underset{(0.152)}{0.157T}, \qquad \bar{R}^2 = 0.861$$

SP: $$\ln MC = \underset{(3.999)}{4.719} - \underset{(0.202)}{0.421\ln PC} - \underset{(0.246)}{0.535\ln DS} + \underset{(0.736)}{1.480\ln Y} + \underset{(0.031)}{0.007T}, \qquad \bar{R}^2 = 0.879$$

RW: $$\ln MC = \underset{(0.531)}{-0.404} - \underset{(0.388)}{0.453\ln PC} + \underset{(0.451)}{0.570\ln PS} - \underset{(0.771)}{0.688DS} + \underset{(0.976)}{3.334\ln Y} + \underset{(0.186)}{0.173T}, \qquad \bar{R}^2 = 0.882$$

Second-Stage

EC: $$\ln(X_{ik}/X_k) = \underset{(0.154)}{-3.451} + \underset{(0.192)}{3.354D_1} + \underset{(0.195)}{1.141D_2} - \underset{(0.708)}{1.587\ln(P_{ik}/P_k)}, \qquad \bar{R}^2 = 0.929$$

SP: $$\ln(X_{ik}/X_k) = \underset{(0.280)}{-4.112} + \underset{(0.402)}{3.713D_1} + \underset{(0.389)}{1.040D_2} - \underset{(1.953)}{6.431\ln(P_{ik}/P_k)}, \qquad \bar{R}^2 = 0.893$$

Note: Numbers in parentheses are standard errors.

tions also appear in tables 1 and 2. EC and SP elasticities of substitution are the coefficients of the P_{ik}/P_k terms of the estimated equations, while D_1 and D_2 are intercept shifters for US and OE exports, respectively. Three out of four estimates are statistically significant at the .05 level or higher, while the t value of the fourth is relatively high. The higher value of the SP estimates reflects greater fluctuations in SP than in EC import origin during the last decade. Since estimates for RW could not be derived, the elasticity of substitution of the region was arbitrarily assumed. This assumption does not affect the overall level of imports to a region; however, it does affect the origin of imports. In turn, this could affect simulation results of the RW exports to EC and SP. But, because the share of RW exports to EC or SP is small (ranging from 1.3% for SP corn imports to 15% for SP soybean imports), the potentially negative impact on model simulations is minimal.

Export supply elasticities were derived from simultaneously estimating the demand for and supply of exports of a region by using the methodology proposed by Goldstein and Khan. In structural form, the estimated system is given by

$$\text{(8a)} \qquad \ln X_t = c_0 + c_1\ln(PX/PXW)_t + c_2\ln YW_t + c_3\ln X_{t-1},$$

$$\text{(8b)} \qquad \ln PX_t = d_0 + d_1\ln X_t + d_2\ln P_t + d_3\ln Y_t + d_4\ln PX_{t-1},$$

where X and PX are quantity and price indexes of exports, PXW and YW are trade weighted in-

Table 2. Estimated Import Demand Equations for Soybeans

First-Stage

EC: $$\ln MS = \underset{(5.405)}{-11.188} - \underset{(0.251)}{0.666\ln PS} + \underset{(0.134)}{0.314\ln PSO} + \underset{(0.389)}{0.525\ln PC} + \underset{(0.792)}{3.936\ln Y} + \underset{(0.112)}{0.389D} - \underset{(0.014)}{0.047T}, \qquad \bar{R}^2 = 0.980$$

SP: $$\ln MS = \underset{(2.566)}{-2.186} - \underset{(0.294)}{1.200\ln PS} + \underset{(0.284)}{0.491\ln PC} + \underset{(0.672)}{2.006\ln Y} - \underset{(0.262)}{0.630T}, \qquad \bar{R}^2 = 0.947$$

RW: $$\ln MS = \underset{(2.249)}{13.524} - \underset{(0.257)}{0.596\ln PS} + \underset{(0.120)}{0.175\ln PC} - \underset{(0.132)}{0.776DS} + \underset{(0.325)}{1.038\ln Y} + \underset{(0.061)}{0.265T}, \qquad \bar{R}^2 = 0.985$$

Second-Stage

EC: $$\ln(X_{ik}/X_k) = \underset{(0.073)}{-3.637} + \underset{(0.100)}{3.225D_1} + \underset{(0.118)}{2.448D_2} - \underset{(1.114)}{2.783\ln(P_{ik}/P_k)}, \qquad \bar{R}^2 = 0.973$$

SP: $$\ln(X_{ik}/X_k) = \underset{(0.223)}{-2.993} + \underset{(0.322)}{2.649D_1} + \underset{(0.321)}{1.336D_2} - \underset{(2.843)}{4.800\ln(P_{ik}/P_k)}, \qquad \bar{R}^2 = 0.670$$

Note: Numbers in parentheses are standard errors.

dexes of the world export price and the importers' real income, P is the domestic price index, and Y is an index of domestic supply, equal to production plus stocks (Haniotis, Baffes, and Ames). Export supply elasticities were recovered from the estimated structural equations as $\beta_i = (1 - d_4)/d_1$. The estimated systems of (8a) and (8b) for the US and OE are reported in table 3. Elasticities of export supply for the United States are 1.11 for corn and 0.29 for soybeans, while for OE the respective elasticities are 1.46 and 2.84. The elasticity of export supply for the EC was assumed to equal its domestic supply price elasticity.[6]

Changes in policy variables implied by the enlargement were simulated by changing the value of $\bar{\tau}_{ik}$ parameters that correspond to the price differential between the export price in the ith exporting region and the import price in the kth importing region. Post-enlargement tariff changes for SP were estimated by weighting corn or soybean tariff changes by the import market share of Spain and Portugal.[7] Finally, price transmission elasticity values (E_{ik}), except for the EC price transmission for corn (whose value was assumed), were obtained from Meyers, Devadoss, and Helmar. In summary, elasticities used in the model simulations are presented in table 4.

Simulation Results

A comparative statics approach was adopted, and the model was simulated in order to compare SP imports of corn and soybeans under the impact of the enlargement to actual trade flows for the base period 1983–85. In order to isolate the impact of the enlargement from the effect of other factors, export and income growth trends were assumed to equal zero. Two sets of scenarios were simulated. First, simulations were performed under the alternative assumptions of incorporating (A) or ignoring (B) the terms of the U.S.–EC agreement on the enlargement dispute. The agreement effect was simulated by assuming that the agreed quota of 2,000 metric tonnes (MT) of corn from all origins would be imported without any changes in tariffs. It was then assumed that the variable import levy would be imposed on corn imports whose volume would equal the difference between a projected pre-enlargement total for SP imports and the amount covered by the quota. Averages for 1983–85 were used for the variable import levy calculation.

Second, simulations were performed by assuming SP elasticity values (ε, e, σ, E) equal to those estimated for the region, which implies the continuation of the pre-enlargement import behavior of the new EC members (a). Alternatively, assuming SP post-enlargement elasticities equal to the estimated EC elasticities implies complete adjustment of the new EC members to the EC import behavior patterns (b).

Results of the model simulations, expressed in terms of percentage changes in trade flows, are reported in table 5. The following general conclusions can be derived from these results. First, the U.S.–EC agreement does have a positive impact for the United States. In both simulated scenarios, decreases in the volume of U.S. corn exports to SP and in total SP corn imports under the agreement assumption (A) are smaller than corresponding decreases under the non-agreement assumption (B). Under the assumption of pre-enlargement SP elasticities (a), the decline in U.S. corn exports to SP is 14% under (A) and 21% under (B), while under the post-enlargement assumption on SP elasticities, relative figures are 24% to 37%, respectively. Similar results apply for total SP corn imports, and for OE exports to SP, while the better performance of RW corn exports is insignificant given that its share of SP corn imports is only 1.3%.

Second, the above results indicate that the negative impact of the enlargement on SP corn imports increases by roughly a third under the assumption that SP import behavior adjusts to EC import patterns (a realistic assumption in view of ongoing adjustments in SP agriculture). Third, the positive impact of the enlargement on SP soybean imports is small under assumption (a), around 3%. However, if post-enlargement elasticities for SP are used (b), then the negative impact of the enlargement on SP corn imports

[6] The extensive use of export restitutions for EC corn exports makes the estimation of an export supply for EC corn nearly impossible. Based on 1966–85 data, the estimated equation of the EC corn supply is

$$\begin{aligned}\ln C = \underset{(2.400)}{7.098} + \underset{(0.522)}{0.880}\ln PC - \underset{(0.113)}{0.266}\ln ST \\ + \underset{(0.094)}{0.126}D + \underset{(0.071)}{0.273}T,\ \bar{R}^2 = 0.875,\end{aligned}$$

where C and ST are the EC production and stocks of corn, PC is the EC real intervention price, D is a dummy variable taking a value of one for the period before the first EC enlargement (1973), and T is time. Use of the domestic EC supply elasticity for corn was considered more appropriate than assuming a perfectly inelastic EC supply response because the analysis focused on post-enlargement SP trade flows.

[7] The weighted average increase in SP corn tariffs was 45%, while for soybeans the corresponding figure was −3%. Pre-enlargement SP import tariffs are found in Friend, Schwartz, and Newman.

Note: Estimated systems are based on 1966–85 data. Standard errors are in parentheses.

is accompanied by a significant, positive effect on SP soybean imports. Under (*Ab*), U.S. soybean exports increase by 6.5%, while the increase is 9% in the scenario assuming that no U.S.–EC agreement had been reached (*Bb*). Finally, the impact of the enlargement on total U.S. corn exports ranges from −1% to −3%, while the impact on U.S. soybean exports is 0.5%.

Based on the above results, it is easy to compute, in volume terms, the enlargement impacts on annual trade flows, and to compare them to average 1983–85 trade flows. Under assumption (*A*), the decline in U.S. corn exports ranges from 469,000 MT (scenario *Aa*) to 828,000 MT (scenario *Ab*). As expected, corresponding decreases under (*B*) are greater, and range from 752,000 MT (*Ba*) to 1.3 million MT (*Bb*). Increases in U.S. soybean exports under assumption (*A*) range from 81,000 MT to 150,000 MT (scenarios *Ab* and *Aa*, respectively), while the no-agreement assumption (*B*) results in increases between 81,000 and 154,000 MT (again under scenarios *Bb* and *Ba*, respectively). Taking the realistic assumption that post-enlargement SP elasticities are equal to average EC elasticities, results indicate that the U.S.-EC agreement, ceteris paribus, decreased U.S. losses of corn exports to SP by one-third, or by over 400,000 MT.

Table 6 summarizes the economic value of gains and losses in U.S. corn and soybean exports to SP under all simulated scenarios. Changes in the value of U.S. exports were computed by using the simulation results and price changes generated from model simulations (changes in export prices for U.S. corn and soybeans are reported in table 5). As expected, corn prices decline and soybean prices increase under the impact of changes in trade flows resulting from the enlargement.

Because of the greater impact of the enlargement on SP corn imports, changes in U.S. ex-

Table 4. Elasticity Values Used in Model Simulations

Elasticity	US	EC	SP	OE	RW
Corn					
ε_k		−0.80	−0.42		−0.45
e_k		0.16			0.57
σ_k		1.59	6.43		2.50
β_i	1.11	0.88		1.46	1.00
E_{ik}		0.25	0.75		0.50
Soybeans					
ε_k		−0.67	−1.20		−0.60
e_k		0.53	0.49		0.18
σ_k		2.78	4.80		2.50
β_i	0.29			2.84	1.00
E_{ik}		0.90	0.85		0.50

Note: ε_k is the own-price elasticity of import demand, e_k is the cross-price import demand elasticity between corn and soybeans, σ_k is the elasticity of substitution, β_i is the export elasticity, and E_{ik} is the price transmission elasticity.

port prices for corn are greater than changes in U.S. export prices for soybeans, and the negative impact of the SP accession on the value of U.S. exports is accentuated. Under assumption (*A*), net losses of U.S. corn and soybeans range between 53 and 88 million U.S. dollars. Under assumption (*B*), net U.S.losses range between $93 million and $144 million. In the most realistic scenario, that assuming the U.S.–EC agreement and the adjustment of SP import behavior to EC patterns, the impact of the enlargement on U.S. corn and soybean exports is a net loss of $88 million or 7% of the average annual value of respective U.S. exports in the pre-enlargement 1983–85 period.[8]

Concluding Comments

This paper utilized the framework of an Armington model to analyze the impact of the European Community enlargement on U.S. corn and soybean exports. Simulating the enlargement impact under alternative assumptions concerning import elasticities of Spain and Portugal resulted in the following conclusions. First, the EC enlargement has a significant and negative impact on U.S. corn exports to the new EC members. However, the U.S.–EC agreement for compensation of U.S. losses of grain exports to Spain and Portugal limited the damage to U.S.

[8] The lack of data on SP imports of non-grain substitutes (whose level was very low before the enlargement) did not allow an assessment of their post-enlargement trade flows. However, significant increases in SP imports for such products recently indicate potential gains for U.S. exports, thus altering the net enlargement impact.

Table 5. Simulated Impact of the EC Enlargement on SP Imports and U.S. Exports and Export Prices of Corn and Soybeans

	Base	A		B	
Scenarios	(1983–85)	*a*	*b*	*a*	*b*
		(percentage changes)

Impact on U.S. export prices					
of corn	129	−1.02	−1.79	−1.53	−2.72
of soybeans	327	0.29	0.56	0.25	0.22

Notes: Annual percentage changes are based on average 1983–85 trade flows. Base quantities are expressed in 1,000 MT and base prices in $/MT. Scenarios: (*A*) with U.S.–EC agreement, (*B*) without U.S.–EC agreement, (*a*) pre-enlargement SP elasticities, (*b*) post-enlargement SP elasticities.

Table 6. Enlargement Impact on Annual U.S. Corn and Soybean Exports to Spain and Portugal (change in million U.S. dollars)

	A		*B*	
Scenario	*a*	*b*	*a*	*b*
Corn exports	−80	−140	−120	−211
Soybean exports	27	52	27	67
Net loss	−53	−88	−93	−144

Note: Scenarios: (*A*) with U.S.–EC agreement, (*B*) without U.S.–EC agreement, (*a*) pre-enlargement SP elasticities, (*b*) post-enlargement SP elasticities.

exports. On the other hand, increases in U.S. soybean exports resulting from the adjustments of SP to the EC zero tariff binding for oilseeds, are much smaller in volume terms.

Second, under the impact of the enlargement, declines in U.S. corn export prices outweigh the insignificant increases in U.S. soybean export prices, and therefore accentuate U.S. losses. *Ceteris paribus,* net losses of U.S. corn and soybean exports to SP are 88 million dollars, or 7% of the pre-enlargement value of U.S. corn and soybean exports to Spain and Portugal. Without the U.S.–EC agreement, these losses would be two-thirds higher in value terms, or 11% of pre-enlargement U.S. exports.

Third, the limited scope of the present analysis does not allow for an evaluation of the structural changes that are expected to occur in the new EC members, and the resulting effects on their import behavior. Nevertheless, the study indicates an important policy implication. In the past, the combination of a protectionist EC grain regime with the free entry of oilseeds in the Community distorted trade flows in a contradictory way by positively affecting U.S. oilseed exports while hurting U.S. grain exports. By generating similar trends, the enlargement has created another source of trade distortion and the potential for further U.S.–EC agricultural trade frictions.

An Adjustment-Cost Rationalization of Asset Fixity Theory

Shih-Hsun Hsu and Ching-Cheng Chang

This article integrates a classic concept in production economics (G. L. Johnson's asset fixity theory) with the dynamic adjustment cost model. Until now the literature has considered these two to be incompatible. By relaxing the smoothness assumption of the adjustment cost function at the origin, the theory of costs of adjustment can provide a rigorous endogenization of asset fixity. G. L. Johnson and Edwards' results are then obtained when the linearity assumption of the adjustment cost function is imposed. The work reported here also indicates that both smoothness at the origin and symmetry of adjustment cost function should be subject to empirical tests.

Key words: asset fixity trap, asset quasi-fixity, asymmetric adjustment cost, discontinuity, Kuhn-Tucker theorem.

The theory of asset fixity (hereafter AFT) was spearheaded by G. L. Johnson (1956) and then developed by Edwards (1959), Hathaway, and Johnson and Quance during the last decade. It has been frequently used to explain the stylized fact of nonreversible supply response in agricultural production. Furthermore, it has also been used in examining why and to what extent assets are fixed in agriculture. G. L. Johnson claims that all the previous analyses either fail to address the depression-prosperity comparison (e.g., the "treadmill theory" by Schultz and Cochrane that focuses only on the prosperous phase of agricultural production) or lack a complete microeconomic basis to build the linkages between asset fixity and nonreversible supply. To handle adequately the impacts of asset fixity on output supply, a generalized version of the neoclassical marginal evaluation principle of the pricing of fixed factors is required.

According to G. L. Johnson (1956), an asset is fixed when its marginal value product in its present on-farm use neither justifies the acquisition of more of it nor its disposition. The bigger the gap between the acquisition cost and salvage value of that resource, the more fixity it possesses.[1] As the factor use is closely related to product supply functions, the linkage between asset fixity and supply response can then be derived from the following hypotheses: When the marginal value in use on the farm is greater than the acquisition cost, it pays to expand (invest). Likewise, if the salvage value exceeds the marginal on-farm value, the farm will contract (disinvest). More often is the case that the marginal on-farm value is between the acquisition and salvage prices. Then, the asset is said to be trapped in its current usage in the farm. Generally speaking, this theoretical framework is a static model coupled with an ad hoc operational definition of a fixed asset by introducing an "acquisition/salvage price differentials" mechanism. But G. L. Johnson's pioneering attempt to endogenize the determination of fixed and variable factors provides a generalization of the neoclassical theory of the firm.

S. H. Hsu is a graduate student, Departments of Mathematics and Economics, and C. C. Chang is a visiting assistant professor, Department of Agricultural Economics, Texas A&M University. Seniority of authorship is shared equally.

This article is partially supported by Texas Agricultural Experiment Station.

The constructive comments and suggestions of Spiro Stefanou on an earlier draft of this article are gratefully acknowledged. In addition, the authors would like to thank Bruce McCarl, James Mjelde, Richard Shumway, James Wilen, and several anonymous *Journal* reviewers for their comments.

[1] Arrow acknowledges the significant divergence between the acquisition cost and salvage value as follows: "From a realistic point of view, there will be many situations in which the sale of capital goods cannot be accomplished at the same price as their purchase. There are installation costs, which are added to the purchase price but cannot be recovered on sale; indeed, there may on the contrary be additional costs of detatching and moving machinery. Again sufficiently specialized machinery and plants have little value to others. So resale prices may be *substantially* below replacement costs" (p. 2). But he went to the other extreme by assuming that investment is always irreversible (in the sense that no disinvestment is allowed). The analysis of disinvestment ($I \leq 0$) is considered a trivial duplicate of the analysis of investment ($I \geq 0$), and thus both the former and AFT have been disregarded in the literature.

Although AFT provides hypothesized linkages between asset fixity and nonreversibility of supply response, its ad hoc operational definition has been subject to criticisms; moreover, it has been difficult empirically to implement the asset evaluation method. The debate over the definition and existence of asset fixity involves both theoretical and empirical points of view. In order to test the asset fixity hypothesis, Chambers and Vasavada (1983) employ a putty-clay technology and apply the Fuss test to U.S. agricultural aggregate data. Their results show no fixity involving capital, labor, or materials in U.S. agriculture. Edwards (1985) argues that the putty-clay technology proposed by Chambers and Vasavada bears no resemblance to the asset fixity proposed by G.L. Johnson 1956, 1960, 1982. Also some degree of disaggregation is required in order to characterize the role of the fixed asset.

M. A. Johnson and Pasour criticize AFT because the opportunity cost of an asset once acquired cannot always be expected to equal its historical acquisition cost which is irrelevant for current decisions. They claim that the efficient asset market should take into account the concept of choice-influencing costs in asset evaluation and the rational producer behavior. Thus, they conclude that AFT is "inconsistent with rational behavior" (p. 3). G. L. Johnson (1982) argues that AFT considers current acquisition costs to be relevant for determining which assets are fixed. Moreover, AFT not only recognizes the importance of opportunity costs in the resource allocation among alternative uses but also clarifies the role of opportunity costs in the neoclassical theory of the firm. Bradford also criticizes M.A. Johnson and Pasour (1981) for ignoring intertemporal opportunity costs of durable resources which are indispensable for a firm's optimal investment/disinvestment decision making.

The recent development in dynamic adjustment cost models shows another direction in modeling asset fixity by stressing sluggishness in input adjustment as a form of asset fixity (Vasavada and Chambers, Taylor and Monson). The empirical applicability of the dynamic adjustment cost model has been useful in identifying the quasi-fixed asset and the magnitude of their quasi-fixity, but their relationship to nonreversibility in output supply and input demand is unclear. Chang and Stefanou further expand the model by incorporating asymmetry in input adjustment. The relationship between asset quasi-fixity and production nonreversibility is established upon the asymmetric adjustment rates of quasi-fixed inputs.

A common weakness in both the symmetric and asymmetric adjustment cost models is the misleading use of quasi-fixity as a form of asset fixity. G. L. Johnson's asset fixity theory emphasizes why an asset is trapped in its current use and results in a "zero" investment. However, the quasi-fixity in the dynamic adjustment cost models suggests a "nonzero" investment (or disinvestment) of an asset through the sluggish adjustment along the firm's optimal expanding (or contracting) production plan. In this sense, asset fixity becomes a missing piece in the literature of costs of adjustment.

The main purpose of this article is to extend the adjustment cost theory of dynamic firm behavior and rationalize the asset fixity theory.[2] It suggests that by relaxing the smoothness assumption of the adjustment cost function at the origin, the theory of costs of adjustment can provide a rigorous endogenization of asset fixity. It is found that because of its static optimization nature, G. L. Johnson and Edwards' model represents the case when the cost of adjustment functions are linear. The linkage between G. L. Johnson's asset fixity theory and the dynamic adjustment cost model is thus established.

The next section lays out the basic model as that analyzed in Rothschild.[3] To sharpen the nature of asset fixity, the linear adjustment cost function then is first considered, and optimal firm behavior under both symmetric and asymmetric specifications is analyzed. Asset fixity then is imbedded in a more general costs of adjustment model. The final section summarizes the results with comments on extensions and future research.

[2] The rationalization of the asset fixity theory is parallel to that of the flexible accelerator using the dynamic adjustment cost model. The flexible accelerator hypothesis provides a theoretical linkage between the long-run desired capital stock which is determined by static theory and the actual observed capital stock through an ad hoc stock adjustment mechanism. Although the simplicity of the flexible accelerator hypothesis has important advantage in empirical work, its ad hoc nature has been subject to criticisms (e.g., Lucas, Gould, Treadway). The dynamic adjustment cost literature (e.g., Eisner and Strotz, Lucas) began with attempts to rationalize this ad hoc flexible accelerator.

[3] The conclusion of this article does not change when other dynamic adjustment cost models are used. For example, Treadway's model (1969) with the imposition of assumptions (2.1)–(2.5) will give similar results but requires the application of maximum principle. Furthermore, generalization to multiple quasi-fixed inputs should provide more insights into AFT but with more complexity. As far as the rationalization of AFT is concerned, Rothschild's model is preferred because of its relative generality and simplicity.

A Dynamic Model of the Competitive Firm

Consider a competitive firm that sells Q units per period of a single product at a unit price P. The product is assumed instantaneously produced using two factors of production, a variable factor called labor services which is hired in a quantity L at a wage rate $W(t)$ and the services of a quasi-fixed factor called capital, a stock K of which incurs a service charge of $G(t)K$ in period t. All markets faced by the firm are assumed competitive and all prices remain constant over the future; that is, the firm holds with certainty static expectations on all prices. The production function $F(K, L)$ is assumed nondecreasing, concave, twice continuously differentiable, has strictly convex isoquants, and satisfies $F(K, 0) = 0$.

Let

$$(1) \quad \nu(K, P, W, G) \equiv \max_{L \geq 0} [(PQ - WL) - GK],$$

where $Q = F(K, L)$ and $\nu(K, P, W, G)$ [or simply $\nu(K)$] represents the maximum profits that the firm gains from having capital stock K in period t. Let the revenue PQ be always bounded above. Since $\nu(K)$ is a strictly concave function of K, it attains an unique maximum on $[0, \infty)$.

The critical remaining assumption is the functional form of the costs of adjustment $C(I)$, where I is the gross investment. It is assumed that

$$(2.1) \qquad C(0) = 0;$$

$$(2.2) \qquad C(I) > 0 \text{ for } I \neq 0;$$

$$(2.3) \quad C'(I) \text{ exists for all } I \text{ except } I = 0, \text{ i.e., } C'(I) \text{ is discontinuous at } I = 0;$$

$$(2.4) \quad \text{both } \lim_{I \to 0^+} C'(I) \text{ and } \lim_{I \to 0^-} C'(I) \text{ exist, but } \lim_{I \to 0^+} C'(I) \text{ is not equal to } \lim_{I \to 0^-} C'(I);$$

$$(2.5) \qquad \text{sign } C'(I) = \text{sign } I \text{ for } I \neq 0.$$

Assumptions (2.1) and (2.2) imply that $C(I)$ has a minimum at 0; hence if $C'(0)$ exists, it must equal 0. Assumptions (2.3) and (2.4) relax the smoothness restriction on $C(I)$. The discontinuity of $C'(I)$ at the origin implies that in the neighborhood of $I = 0$ the adjustment cost of investment, e.g., installation costs, cannot be recovered on sale (when disinvestment occurs); conversely, the adjustment cost of disinvestment, e.g., costs of detatching and moving machinery, cannot be recovered when investment occurs.[4,5] Loosely speaking, this recognizes the existence of the gap between the acquisition cost and salvage value. Furthermore, we do not restrict our attention to convex adjustment cost functions. Other forms of adjustment cost function (e.g., linear, concave, and piecewise convex or concave) are also allowed.

Suppose that the firm can borrow or lend in a competitive capital market at a positive, constant interest rate r. At any point in time $t = 1$ (called a base period), this price-taking firm chooses the sequence of investment $I = [I_1, I_2, \ldots]$ to maximize the following infinite horizon problem:

$$(3) \quad \mathcal{T}(K_0, I, P, W, G) \equiv \sum_{t=1}^{\infty} [\nu(K_t, P, W, G) - C(I_t)](1 + r)^{-t},$$

subject to

$$(4) \quad K_t = K_{t-1} + I_t \qquad t = 1, 2, \ldots, K(0) = K_0 > 0.$$

Because the introduction of depreciation into this model will not alter the results, depreciation is ignored. As the base period changes and new market prices are observed, the firm revises its expectations and its previous plans; hence in general only the $t = 1$ part of the plan corresponding to (3) and (4) is carried out.

Only necessary conditions are emphasized in this article. Sufficient conditions to ensure the existence of an optimal solution can be found in Rothschild.

The Linear Costs of Adjustment and Optimal Firm Behavior

In order to delineate the relationship between the asset fixity theory and the theory of costs of adjustment, the linear adjustment cost function is

[4] A similar phenomenon was conjectured by G. L. Johnson when he wrote, "Every farm boy knows that selling such assets or the services they produce is quite a different matter from buying them. *Discontinuities* are far more characteristic than perfect elasticities" (G. L. Johnson 1960, p. 27).

[5] The concept of costs of adjustment is so primitive such that its economic interpretation is quite flexible. For example, transportation, risk, legal fees, brokerage, spoilage, contracting, insurance, and other like costs are also involved. This kind of flexibility is indeed one of the sources of its power.

first considered.[6] Also, this section will discuss both symmetric and asymmetric adjustment cost functions, analyze their respective implications on optimal firm behavior, and stress the importance of the behavior of $C(I)$ at the origin in determining the nature of the firm's investment program.

Suppose adjustment cost functions are linear, e.g.,

$$(5)\qquad C(I) = \begin{cases} aI & \text{if } I \geq 0, \\ -bI & \text{if } I \leq 0; \end{cases}$$

where $a > 0$, $b > 0$. See figure 1. The kink at the origin indicates that $C'(I)$ is not continuous at $I = 0$. But both left-hand and right-hand limits of $C'(0)$ exist, and $\lim_{I\to 0^-} C'(I) = -b$, $\lim_{I\to 0^+} C'(I) = a$.

Because of the linearity of the adjustment cost function, the firm saves nothing by slow adjustment; hence, all the adjustment (either investment or disinvestment) will be bunched in the first period only (see theorem III in Rothschild, p. 617). Thus, $I_2 = I_3 = \ldots = 0$ and $K_1 = K_2 = K_3 = \ldots$. The optimal investment program is found by solving the following control problem:

$$(6)\qquad \begin{cases} \max \mathcal{T}(K_0, I) \text{ subject to } I_t \geq 0, \\ \max \mathcal{T}(K_0, I) \text{ subject to } I_t \leq 0; \end{cases}$$

where

$$\begin{aligned}(7)\quad \mathcal{T}(K_0, I) &= \sum_{t=1}^{\infty} [v(K_{t-1} + I_t)(1 + r)^{-t} \\ &\quad - C(I_t)(1 + r)^{-t}] \\ &= v(K_0 + I_1) \sum_{t=1}^{\infty} (1 + r)^{-t} \\ &\quad - C(I_1)(1 + r)^{-1} \\ &= (1 + r)^{-1} [v(K_0 + I_1) \\ &\quad \cdot \frac{(1 + r)}{r} - C(I_1)].\end{aligned}$$

By the Kuhn-Tucker Theorem, if I_1^* (or simply I^*) is the optimal investment, it follows that

$$(8)\qquad \begin{Bmatrix} \mathcal{T}'(K_0, I^*) \leq 0 \text{ and } I^*\mathcal{T}'(K_0, I^*) = 0, \\ \mathcal{T}'(K_0, I^*) \geq 0 \text{ and } I^*\mathcal{T}'(K_0, I^*) = 0, \end{Bmatrix} \text{ when } \begin{cases} I^* \geq 0 \\ I^* \leq 0, \end{cases}$$

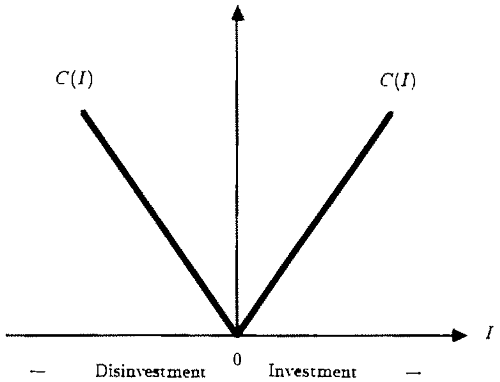

Figure 1. Linear symmetric adjustment cost function

where $\mathcal{T}'(K_0, I^*)$ denotes the derivative of $\mathcal{T}$ with respect to I and is evaluated at I^*. This derivative may not exist at $I^* = 0$ but both $\lim_{I^*\to 0^-} \mathcal{T}'(K_0, I^*)$ and $\lim_{I^*\to 0^+} \mathcal{T}'(K_0, I^*)$ exist.

Equation (8) implies a two-stage decision process: (stage I) whether to adjust or not (i.e., $I^* \neq 0$ or $I^* = 0$), and (stage II) by how much. By combining equations (7) and (8) with the discontinuity of the $C'(I)$ at the origin, the stage I decision rule can be derived as follows: Whenever

$$(9.1)\qquad \left(\frac{r}{1 + r}\right) \lim_{I\to 0^-} C'(I) < v'(K_0 + I^*) < \left(\frac{r}{1 + r}\right) \lim_{I\to 0^+} C'(I);$$

or, in this example,

$$(9.2)\qquad -b\left(\frac{r}{1 + r}\right) < v'(K_0 + I^*) < a\left(\frac{r}{1 + r}\right),$$

no adjustment is needed, i.e., $I^* = 0$, and the initial capital stock K_0 is fixed. The difference between $(r/1 + r) \lim_{I\to 0^-} C'(I)$ and $(r/1 + r) \lim_{I\to 0^+} C'(I)$ can be viewed as the "asset fixity trap" which is conjectured by G. L. Johnson (1982) when they assert that an asset is fixed if on-farm opportunity costs are bounded by off-

[6] Similar results in this section can be obtained when the cost of adjustment function is concave. In this case the best policy for the firm would be to take advantage of decreasing marginal cost of adjustment (either investment or disinvestment) and concentrate its response to changes in market conditions in a single period.

farm opportunities for acquisition and salvage or "if it ain't worth varying." (Edwards 1959, p. 749)

If $v'(K_0 + I^*)$ is not locked inside the asset fixity trap, i.e., the initial capital stock K_0 is not viewed as a fixed asset, then $I^* \neq 0$ and the stage II decision determines the extent of investment or disinvestment. From equation (8), the optimal adjustment I^* must be a solution to the equation $\mathcal{F}'(K_0, I) = 0$. As a result, the decision rule can be characterized as follows:

$$(10.1)\quad v'(K_0 + I^*) = \left(\frac{r}{1+r}\right) C'(I^*);$$

or, in our case,

$$(10.2)\quad v'(K_0 + I^*) = \left\{\begin{matrix} a\left(\frac{r}{1+r}\right) \\ -b\left(\frac{r}{1+r}\right) \end{matrix}\right\} \text{ if } \left\{\begin{matrix} I^* > 0, \\ I^* < 0. \end{matrix}\right.$$

When investment (or disinvestment) is needed, marginal cost of adjustment must be equated to marginal present value. Thus conditions (10.1) and (10.2) resemble the familiar marginal principles of neoclassical production theory. Traditionally, the role of opportunity costs in neoclassical theory has been disciplined to generate the stage II decision rule. Therefore, it is clear that, contrary to M.A. Johnson and Pasour's (1981) assertion, asset fixity theory does not ignore the importance of opportunity costs but rather clarifies their role in the neoclassical theory of firm.

Symmetric Costs of Adjustment: (a = b)

The optimal firm behavior is illustrated by figure 2. For simplicity, we assume that $v'(K_0 + I)$ is linear in I. Also notice that the LHS of equation (10.1) is a decreasing function of I and the whole schedule $v'(K_0 + I)$ will shift downwards as the initial stock K_0 increases. Let K_0^i,

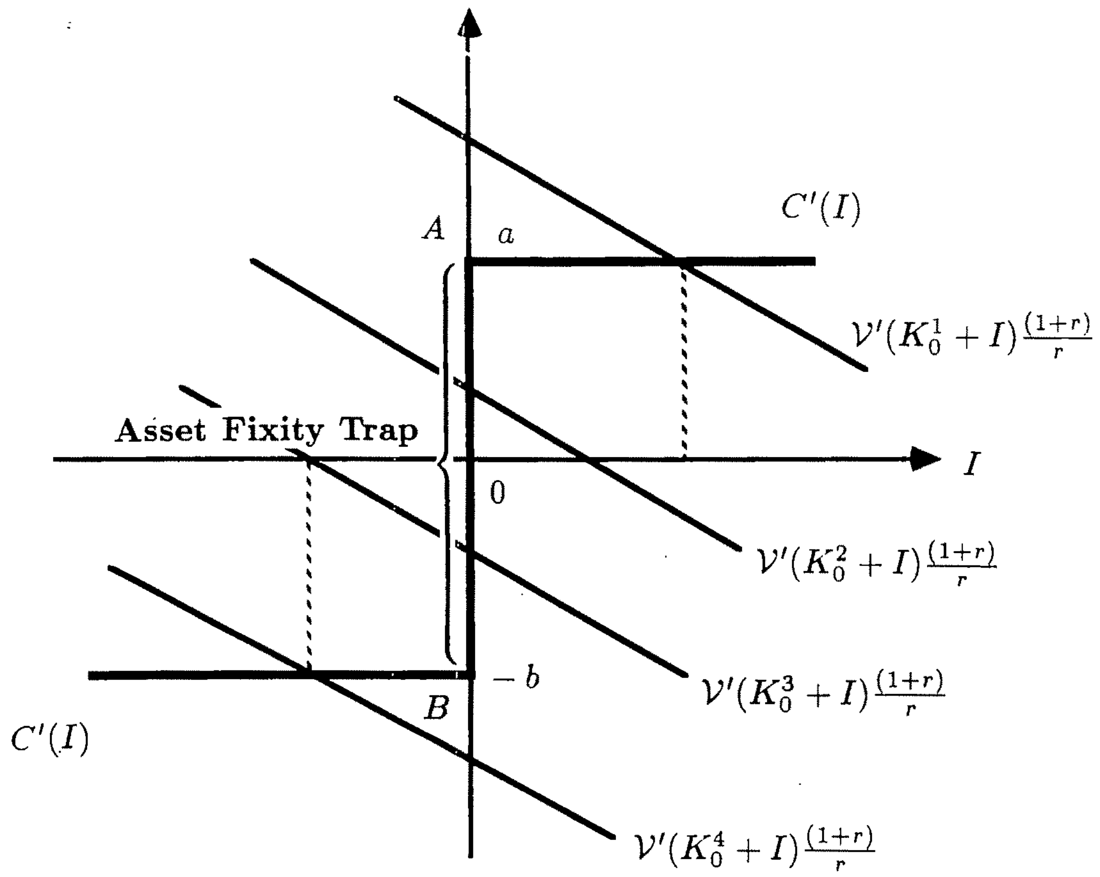

Figure 2. Optimal behavior with linear symmetric adjustment cost

($i = 1, 2, \ldots$) denote different initial stocks where $K_0^i < K_0^j$ if $i < j$. AC, SV, and $v'(K_0 + I)$ schedules can be viewed as the generalized concepts of acquisition cost, salvage value, and marginal value product of I, respectively. See the similarities between figure 2 and Edwards' figure 1 (p. 751) except that here the picture has been translated to the origin due to the "flow" concepts of investment and disinvestment.

Figure 3 is the phase diagram which describes the scenarios of dynamic adjustment process toward equilibrium (Treadway 1970). With the existence of the asset fixity trap, the equilibrium is no longer unique. From equation (9.2), a conceivable range of capital stock levels is allowed for the case of no adjustment ($I^* = 0$), which is shown by the section between points A and B. If the initial market conditions are such that the current capital stock falls inside the asset fixity trap AB, the asset is considered in equilibrium and no adjustment is necessary. Once the market conditions (e.g., prices) change or the firm modifies its expectations, the current stock level may fall outside the trap and adjustment may occur (as the case where K_0 is located at K_0^1 and K_0^4). Thus, an asset can be viewed as putty in the first period, clay in the second period, then putty again in the third period, and so on. In this sense, a simple putty-clay technology as suggested by Chambers and Vasavada (1983) cannot be compared with the asset fixity hypothesis.

In general, inside the asset fixity trap, small changes in market conditions will not cause any adjustment. If we impose the symmetry assumption on the costs of adjustment functior (i.e., $a = b$) like figure 1, the analysis indicate: that producers have the same responses to both price increases and price decreases when inside and outside the asset fixity trap. See figure 2. However, this cannot explain the fact that U.S. agricultural production displays a greater capacity to expand than to contract.

Asymmetric Costs of Adjustment: ($a \neq b$)

Without loss of generality, we assume $a < b$ for the case where it costs more to contract than to expand (see fig. 4).[7] Inside the asset fixity trap AB in figure 5, AO is much shorter than OB. It appears that the tendency to expand is much more sensitive to market conditions than that to contract. For example, with the initial K_0^2, the firm may plan to invest in response to a favorable market situation. On the other hand, with the same K_0^2, a more dramatic change in market conditions is required for the firm to disinvest. This asymmetric case provides a better explanation of Johnson's hypothetical link between asset fixity and nonreversible supply response than the symmetric one.

The Convex Costs of Adjustment and Optimal Firm Behavior

The concept of asset fixity can be easily imbedded into more general costs of adjustment models

[7] It is also possible that $a > b$. This firm, for example, may have accumulated knowledge from previous experience such that he (or she) has greater capabilities to contract than to expand in response to unfavorable market situations.

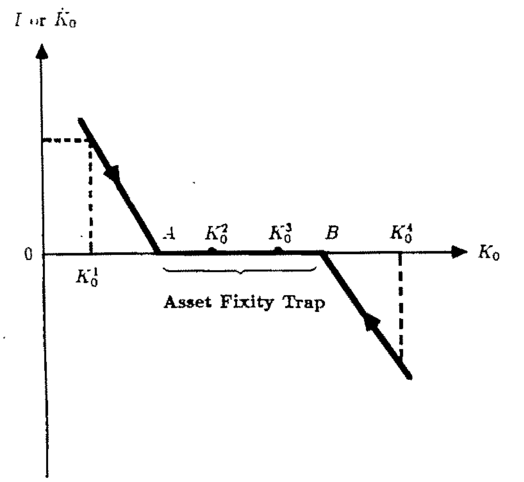

Figure 3. Phase diagram of capital stock adjustment

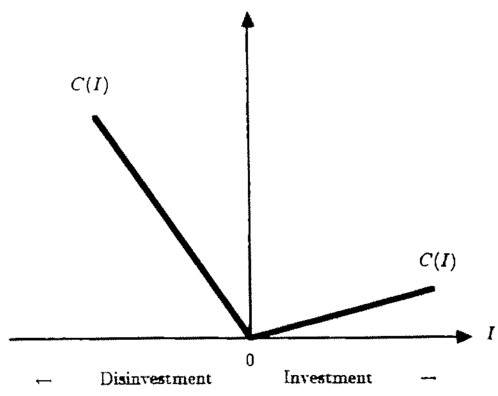

Figure 4. Linear asymmetric adjustment cost function

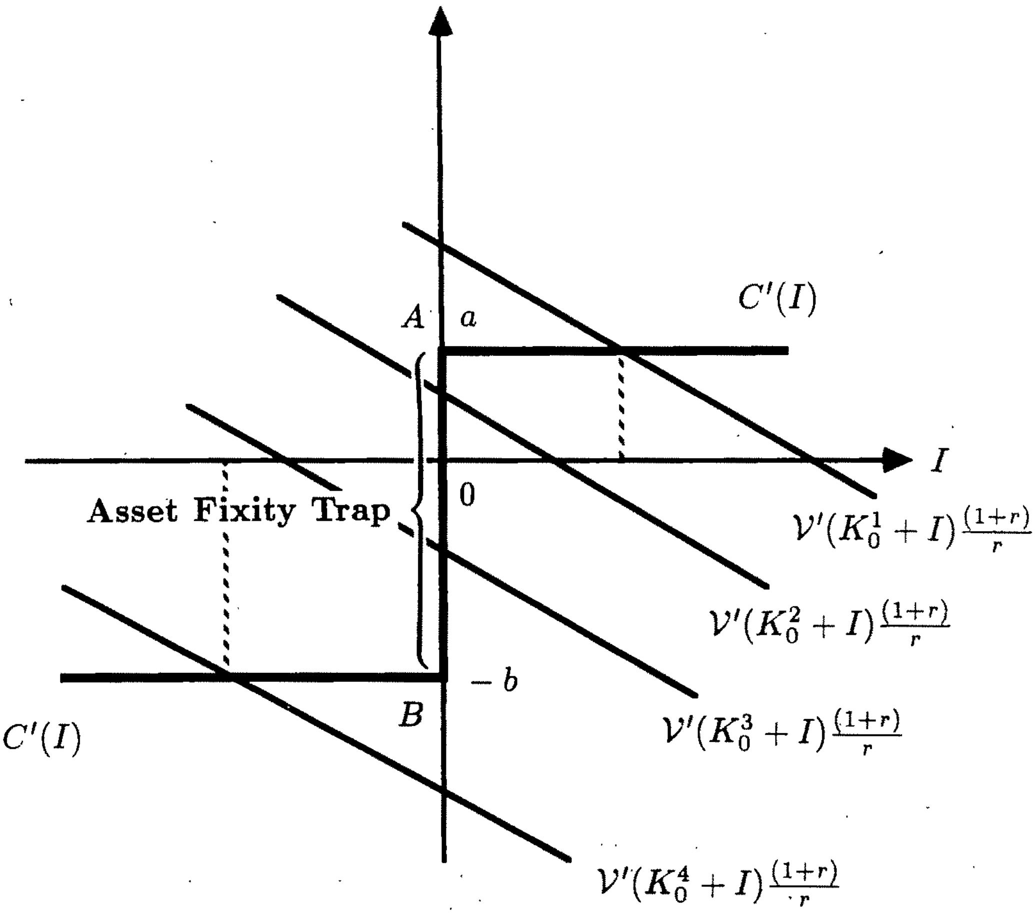

Figure 5. Optimal behavior with linear asymmetric adjustment cost

Because the quadratic ones are widely adopted in the literature, this section deals solely with a generalized version of quadratic adjustment cost function of the form

(11)
$$C(I) = \begin{cases} a\left(I + \sqrt{\dfrac{b}{a}}\right)^2 - b, & \text{if } I \geq 0, \\ c\left(I - \sqrt{\dfrac{d}{c}}\right)^2 - d, & \text{if } I \leq 0; \end{cases}$$

where $a > 0$, $b \geq 0$, $c > 0$, and $d \geq 0$. Clearly, this function satisfies all the assumptions in (2).

Nonsmoothness of C(I) at the Origin:

Let $b > 0$ or $d > 0$ and the function is shown in figure 6. Obviously $C'(I)$ exists for all I except when $I = 0$. Here $\lim_{I\to 0^+} C'(I) = 2\sqrt{ab}$ and $\lim_{I\to 0^-} C'(I) = -2\sqrt{cd}$. It turns out that $\lim_{I\to 0^-} C'(I) < \lim_{I\to 0^+} C'(I)$. Since $C(I)$ is strictly convex, theorem II of Rothschild (p. 616) applies: If the firm responds at all to changes in market conditions, it will distribute its response over all periods; that is, if there is investment in the first period, $I_1 \neq 0$, then $I_2 \neq 0$, $I_3 \neq 0$, ... Thus, of particular importance is the first period in which an intertemporal decision is made and all future returns of I_1 must be considered.

Analogous to the dynamic optimization problem in the preceding section, it follows that the firm faces the following situation:

(12)
$$\begin{cases} \text{Max } \mathcal{T}(K_0, I) \text{ subject to } I_t \geq 0, \\ \text{Max } \mathcal{T}(K_0, I) \text{ subject to } I_t \leq 0; \end{cases}$$

where

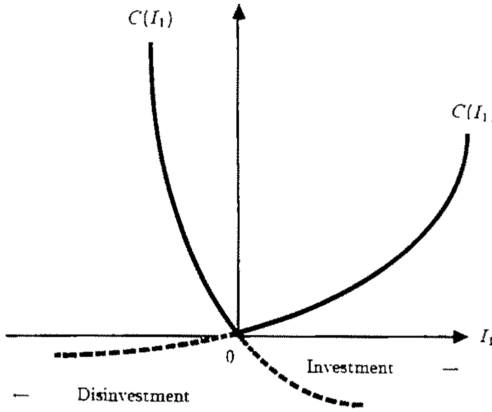

Figure 6. Quadratic asymmetric adjustment cost function

$$(13) \quad \mathcal{T}(K_0, I) = \sum_{t=1}^{\infty} [\nu(K_0 + I_1 + \ldots + I_t) \cdot (1 + r)^{-t} - C(I_t)(1 + r)^{-t}].$$

Let $I^* = [I_1^*, I_2^*, \ldots]$ be the optimal future plan decided in the first period. From the Kuhn-Tucker Theorem the stage I decision rule at period 1 is developed as follows: Whenever

$$(14.1) \quad \lim_{I_1 \to 0^-} C'(I_1) < \sum_{t=1}^{\infty} \nu'(K_0 + I_1^* + \ldots + I_t^*) \cdot (1 + r)^{-t+1} < \lim_{I_1 \to 0^+} C'(I_1);$$

or, combined with the specification of (11),

$$(14.2) \quad -2\sqrt{cd} < \sum_{t=1}^{\infty} \nu'(K_0 + I_1^* + \ldots + I_t^*) \cdot (1 + r)^{-t+1} < 2\sqrt{ab},$$

no adjustment (investment or disinvestment) will occur, that is, $I_1^* = 0$ and $I^* = 0$. Therefore, K_0 is trapped in the production and is viewed as fixed. The difference between $\lim_{I \to 0^-} C'(I)$ and $\lim_{I \to 0^+} C'(I)$ leads to the phenomenon of the asset fixity trap as in the linear costs of adjustment case.

If $I_1^* \neq 0$, that is, if $\Sigma_{t=1}^{\infty} \nu'(K_0 + I_1^* + \ldots + I_t^*)(1 + r)^{-t+1}$ is outside the asset fixity trap, then I_1^* should satisfy the following marginal principle rule:

$$(15.1) \quad \sum_{t=1}^{\infty} \nu'(K_0 + I_1^* + \ldots + I_t^*) \cdot (1 + r)^{-t+1} = C'(I_1^*);$$

or, in our case,

$$(15.2) \quad \sum_{t=1}^{\infty} \nu'(K_0 + I_1^* + \ldots + I_t^*)(1 + r)^{-t+1} = \begin{Bmatrix} 2(aI_1^* - \sqrt{ab}) \\ 2(cI_1^* - \sqrt{cd}) \end{Bmatrix} \text{ if } \begin{cases} I^* > 0, \\ I^* < 0. \end{cases}$$

An interpretation similar to the linear case can be drawn from figure 7. Of particular interest is the appearance of asymmetry in both the asset fixity trap, AB, and quasi-fixity along $C'(I_1)$. Here it may suffice to quote G.L. Johnson and Quance: "Irreversibility is taken to mean responses to price decreases which are not the exact opposites of corresponding increases. Generally, the theoretical output responses to product price increases should be expected to exceed the contractions associated with product price declines. Similarly, expansions in use of inputs resulting from product price increases and input price decreases should be expected to be greater than the contractions resulting from comparable product price declines and input price increases" (pp. 190–91). As a result, when asset fixity is coupled with a second-best allocative efficiency mechanism to minimize losses after an initial error (Johnson and Quance, chap. 4; G. L. Johnson 1982, p. 774), this type of asymmetric adjustment cost model can provide a better factual and analytical basis for the overproduction trap in U.S. agriculture.

Both nonsmoothness at the origin and asymmetry of $C(I)$ have important implications in explaining the traditional farm adjustment problem. Unfortunately, the former has been ignored by almost all the literature on adjustment cost models and their corresponding empirical applications. Only Rothschild comes close to this point by emphasizing the importance of the behavior of the adjustment cost function near the origin in determining the nature of the firm's investment decision. However, it is the behavior at the origin which brings in the recognition of a fixed asset and its degree of fixity.

Smoothness of C(I) at the Origin:

When $b = d = 0$ and $a = c$, $C(I)$ in equation (11) reduces to the popular one in the literature (e.g., Gould, pp. 48–49; Sargent, p. 133). Here, $C(I)$ is continuously differentiable everywhere; in particular, $C'(0)$ exists and equals to 0. See figure 8. Thus,

$$\lim_{I \to 0^-} C'(I) = \lim_{I \to 0^+} C'(I) = 0,$$

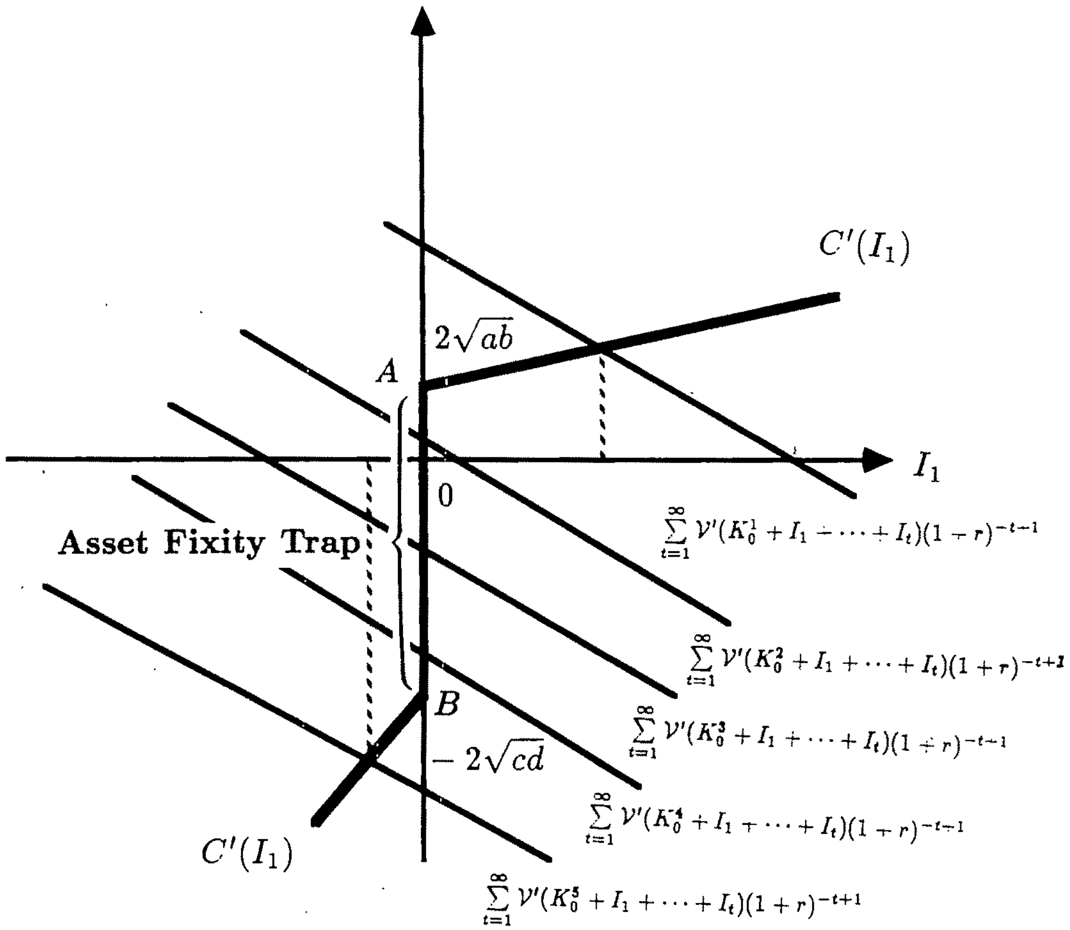

Figure 7. Optimal behavior with quadratic asymmetric adjustment cost

and the asset fixity trap disappears altogether in figure 9. The firm then will respond to almost any change in market conditions; that is, nothing is fixed. However, some degree of sluggishness in factor adjustment can still be captured in terms of asset quasi-fixity. Similar arguments can be drawn from more general cost of adjustment functions. Hence, unless the smoothness assumption of $C(I)$ at the origin is relaxed, such specifications, either symmetric or asymmetric, can at most be justified in explaining asset quasi-fixity rather than the real asset fixity proposed by Johnson.

Concluding Comments

Existing rationalizations of asset fixity theory have been incomplete because they have relied on static models coupled with an ad hoc acquisition/salvage price differentials hypothesis. This article has clarified the theory of asset fixity through the introduction of dynamic adjustment cost.

The principal conclusions of the analysis are the following: First, by inspecting the asset fixity theory under the dynamic adjustment cost framework, one can obtain a theory which is much richer in its implications for the asset fixity and asset quasi-fixity. Because of the static nature of their model, Johnson and Edwards' results are obtained when the linearity assumption of the costs of adjustment function is imposed. Second, from the above discussion, the costs of adjustment theory provides not only a theoretical justification for the use of distributed lags in econometric studies of investment but also a rigorous endogenization of asset fixity. In this sense, the costs of adjustment theory is a further generalization of the neoclassical analysis and hence is indispensable for a complete "theory of in-

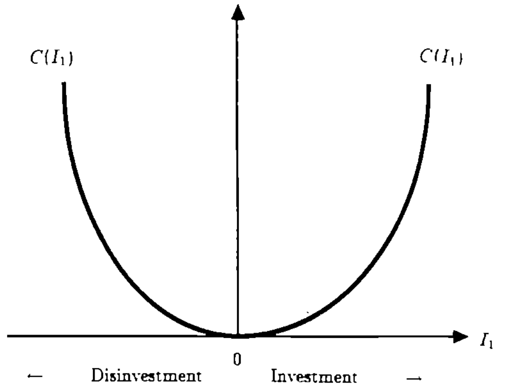

Figure 8. Quadratic symmetric adjustment cost function

vestment/disinvestment" in the sense of G. L. Johnson (1982, p. 775).

Third, it is not the behavior of $C(I)$ near the origin, either convexity or concavity, which guarantees the existence of asset fixity but the discontinuity of $C'(I)$ at the origin. Without this crucial specification the popular quadratic cost function can only capture some degree of sluggishness of factor adjustment in terms of asset quasi-fixity, but not asset fixity. This is one of the important reasons why most theoretical work on the theory of adjustment cost has had little or no impact on empirical investigations of asset fixity. Therefore, tests of asset fixity using conventional econometric techniques are doomed to failure. No wonder Chambers and Vasavada (1985, p. 139) assert that "the theory (of asset

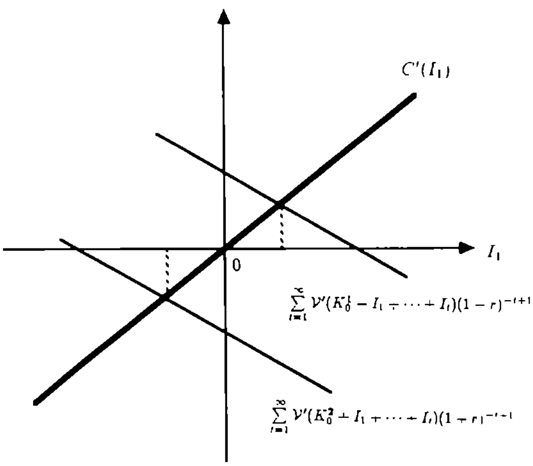

Figure 9. Optimal behavior with quadratic symmetric adjustment cost

fixity) still remains untested and, as such, appears to border on what Joan Robinson has defined as a metaphysical proposition."

The work reported here also implies that both smoothness of $C(I)$ at the origin and symmetry of $C(I)$ should be subject to empirical tests. Although the underlying analysis is carried out at the micro level, it has important implications for aggregate studies on supply response and investment (or disinvestment) behavior. The literature on estimating nonreversible supply functions (Tweeten and Quance; Wolffram; Houck; Traill, Colman, and Young) utilize a price-segmenting method to specify the aggregate supply response model. An appealing econometric extension of the research on asset fixity is to incorporate the segmenting idea into the cost of adjustment function. The further expansion to allow for regime changes and asymmetric response will enrich the contents of the dynamic model in terms of empirical applications. Also deservedly dominating our attention are equations (10.1) and (10.2) which are piecewise continuous differential equations with the right-hand side discontinuities. Such kind of equations are the major concern of the variable structural system (VSS) approach.[8] To avoid the aggregation difficulties with AFT (Edwards 1985, p. 136), the VSS approach endogenously partitions the intertemporal decision-making problem into two subsystems: one is in the expansion (i.e., investment) regime; the other is in the contraction (i.e., disinvestment) regime. The analysis of the firm's optimization behavior in these two regimes ($I^* \neq 0$) may provide insight for unveiling the mysteries of asset fixity trap ($I^* = 0$) (e.g., Chang and Stefanou).

Farmers' Marginal Propensity to Consume: An Application to Illinois Grain Farms

Michael R. Langemeier and George F. Patrick

The marginal propensity to consume (MPC) for a sample of eighteen Illinois farms over the 1979–86 period is determined. Four consumption models were estimated using disposable household income plus depreciation as the measure of income. Estimated short-run MPCs ranged from 0.007 to 0.020, while long-run MPCs varied between 0.143 to 0.381. These results indicate farm family consumption responded little to changes in income and that the life cycle hypothesis model explains consumption significantly better than the other models. Robustness of the results is demonstrated using a larger sample of farms for 1986–87.

Key words: farm consumption, income volatility, marginal propensity to consume.

Consumption behavior of a farm family affects firm growth, debt repayment, and the firm's responses to policy changes. Pederson and Brake gave two important reasons for including family living expenditures in financial analysis: (*a*) family consumption reduces the firm's ability to acquire assets; (*b*) family living expenditures are a measure of the farm family's standard of living. Policy analysts are also interested because farmers' consumption behavior affects the reaction of input use, investment, and debt repayment to changes in agricultural and economic policy.

Empirical studies on the relationship between farm consumption and income are not prevalent because of the sparsity of high quality data on family living expenditures. Previous studies that have estimated consumption functions based on individual farm observations include MacMillan and Loyns; Girao, Tomek, and Mount; Leon and Rainelli; Mullen, Powell, and Reece; and Beck and Dent. Of these, only the Girao, Tomek, and Mount study analyzed the consumption behavior of U.S. farmers. The data used in their study are now almost twenty years old. Since then the farm economy has undergone substantial change.

The purpose of this study is to determine the marginal propensity to consume for a sample of Illinois farms for the 1979–86 period. Models based on the partial adjustment, relative income, permanent income, and life cycle hypotheses are used to estimate the marginal propensity to consume. A larger cross section of Illinois farms for 1986–87 is used to evaluate the robustness of the results. Implications of the estimated marginal propensities to consume are then discussed.

Consumption Hypotheses and Models

If farm consumption is less volatile than income, there may be some inertia or habit persistence in farm consumption and the marginal propensity to consume will be relatively low. Habit persistence indicates previous consumption would have a significant influence on current consumption. Consumption lagged one period was used to model habit persistence by Hall and by Sargent.

Several theories have been postulated to explain habit persistence in consumption. Though the models are similar, the way in which habit persistence is modeled differs slightly. In addition to lagged consumption, income and wealth

Journal Paper No. 12,096 Indiana Agricultural Experiment Station, Purdue University.

The data used in this study were provided by Charles Cagley and Dale Lattz of the Illinois Farm Business-Farm Management Association. Appreciation is expressed to Deborah Brown, Tim Baker, and especially to Wade Brorsen for helpful comments on preliminary versions of this paper.

are typically hypothesized to have a significant influence on consumption. Recent studies have also included socioeconomic characteristics of the household as variables (Mullen, Powell, and Reece).

Variables used in the discussion below have the following definitions: C is real consumption, IBD is real disposable household income plus depreciation, IBD_o is previous peak level of real disposable household income plus depreciation, PI is real permanent income, NW is real net worth, e is an error term, and t, $t-1$ as subscripts refer to years.

One approach used in modeling habit persistence is the partial adjustment hypothesis. Consumers are assumed to adjust consumption only partially when income fluctuates because of habit or lack of information. The actual change in C from $t-1$ to t is some function of the desired change between periods. Johnston shows that the partial adjustment model can be estimated as

$$(1) \qquad C_t = a_0 + a_1 IBD_t + a_2 C_{t-1} + e_t,$$

where a_0, a_1, and a_2 are regression coefficients. Socioeconomic variables, such as size of the household (HS), age of the head of the household (A), and age of the oldest child (CH), could be added as explanatory variables.

A second model to explain habit persistence is the relative income hypothesis. This hypothesis was developed by Duesenberry to explain variation in the C/I ratio. Duesenberry hypothesized the rich spend proportionally more because of emulation. In addition, individuals become accustomed to a certain standard of living and find it difficult to reduce consumption when income decreases. A model of the form

$$(2) \qquad C_t = b_0 + b_1 IBD_o + b_2(IBD_t - IBD_o) + e_t$$

was used by Mullen, Powell, and Reece to test the relative income hypothesis in Australia. In this equation b_0, b_1, and b_2 are coefficients to be estimated. The coefficient on b_1 and b_2 represent the long-run and short-run marginal propensities to consume, respectively. A lagged consumption variable is not included in equation (2). The previous peak income variable is used instead of lagged consumption to model habit persistence.

A third approach to model habit persistence is the permanent income hypothesis. Friedman distinguished between permanent and transitory components of income and consumption. Permanent consumption was hypothesized to be a function of permanent income. Friedman suggested that permanent income be estimated by a weighted average of current and past income and that measured consumption be used as a proxy for permanent consumption. The model becomes

$$(3) \qquad C_t = c_0 + c_1 PI_t + c_2 C_{t-1} + e_t,$$

where c_0, c_1, and c_2 are regression coefficients. A weighting scheme of $1/2\ IBD_t + 1/3\ IBD_{t-1} + 1/6\ IBD_{t-2}$ is used to model permanent income. Beck and Dent used this weighting scheme to model permanent income. Alternatively, the permanent income hypothesis could be estimated using the adaptive expectations mechanism.

A fourth model to explain habit persistence is the life cycle hypothesis developed by Ando and Modigliani. This hypothesis assumes a consumer's utility is a function of current and future consumption. Utility is maximized subject to current and future earnings and current net worth. Ando and Modigliani suggest using current income as a proxy for future earnings. The life cycle hypothesis can be estimated with the following equation:

$$(4) \qquad C_t = d_0 + d_1 IBD_t + d_2 C_{t-1} + d_3 NW_t + e_t,$$

where d_0, d_1, d_2, and d_3 are regression coefficients.

The four models discussed above are used to estimate the marginal propensity to consume for a sample of Illinois farms. Based on the theoretical models, all of the regression coefficients should be positive. Also, if the income stream of the sample of farms is volatile, the estimated marginal propensities to consume will be relatively small (Friedman). Non-nested hypotheses tests will determine if any of the theoretical models explain consumption significantly better than the others.

Consumption and Income for a Sample of Illinois Farms

Data for this study were obtained from records of families enrolled in Farm Business-Farm Management Associations in Illinois. A subsample, about 325 in 1986, of all cooperating families keep track of the sources and uses of funds. To be considered usable, records must satisfy a number of checks designed to insure completeness and accuracy.

This study used only the eighteen farms that

had usable data for each year from 1979 to 1986. In 1986 these eighteen predominately grain farms had an average of 818 tillable acres, of which 119 acres were owned. The number of tillable acres on these eighteen farms was about 26% greater than the mean of the larger group in 1986, while the acres owned was about 4% less. The average ages of the operator and oldest child were forty-five and thirteen years, respectively, in 1986. The average household size was 3.8 people.

Table 1 presents information on real average annual consumption, disposable household income, disposable household income plus depreciation, and net worth. These series were inflated to 1986 dollars using the implicit price deflator for personal consumption expenditures (U.S. Dept. of Commerce). Average annual total consumption was approximately $32,000 per farm, about 11% above the 1986 average for the 325 farms on which sources and uses of funds are kept.[1]

Disposable household income (net farm income plus net nonfarm income minus taxes) over the period was considerably more variable than consumption, indicating consumption only partially adjusts when income fluctuates.[2] An alternative measure of income, disposable household income plus depreciation, was more closely related to actual funds available for consumption and was less variable than disposable household income.

Consumption exceeded disposable household income on only two farms in 1979, while ten to fifteen farms were in this situation from 1981 to 1984. Consumption is just one of many possible uses of funds. Over the period, consumption exceeded disposable household income by $2,000 per year. In contrast, disposable household income plus depreciation was about $27,500 more than consumption annually. Thus nontaxable receipts, money borrowed, and depreciation were used, in addition to disposable household income, for family living. Average real net worth

[1] Average real total consumption for all farms that kept track of sources and uses of funds in 1979, 1980, 1981, 1982, 1983, 1984, 1985, and 1986 was $33,885, $30,691, $31,299, $28,413, $29,066, $28,220, $27,786, and $28,742, respectively. The total number of farms that kept track of sources and uses of funds varied over the period.

[2] Mean net nonfarm income on these farms was about 22% of net farm income over the period. Nonfarm income was slightly less variable than farm income over the period.

Table 1. Means and Standard Deviation (in 1986 Dollars) of Real Consumption, Income, and Wealth for Eighteen Illinois Farms, 1979–86

Year	Total Consumption	Disposable Household Income	Disposable Household Income Plus Depreciation	Net Worth	Number[a]
1979	32,244[b]	68,894	100,617	330,476	2

[a] Number of farms in which consumption exceeded disposable household income.
[b] Arithmetic mean for the 18 farms in real terms.
[c] Standard deviations are in parentheses.

per farm peaked in 1980 and declined from 1981 to 1986.[3]

The empirical evidence in table 1 supports the hypothesis of inertia or habit persistence in farm consumption. The coefficient of variation (standard deviation divided by mean) of consumption was 10% of disposable household income and 20% of disposable household income plus depreciation for the sample of farm families. In the analysis below, disposable household income plus depreciation is used as the income measure.

Pooling Time-Series and Cross-Section Data

A pooled data set contains observations over time and over cross sections. A number of different econometric models can be used with pooled data (Kmenta). The econometric model used in this study is the cross-sectionally correlated and timewise autoregressive model described by Kmenta (pp. 622–25). Specifically, the assumptions are that the variance of the error terms for each cross section or family unit differ, the error terms for each cross section are correlated with the error terms of the other cross sections and first-order autocorrelation. The error structure of the model is not known, so an estimated generalized least squares (GLS) approach is needed.

The following test statistic is used to test the null hypothesis of no first-order autocorrelation:

$$Q = T \sum_{k=1}^{n} \hat{r}_k^2, \tag{5}$$

where r is the sample autocorrelation coefficient for each cross section, T is the number of observations in each cross section, n is the number of cross sections, and k represents a cross section. The estimated rho values (first-order autocorrelation statistics) for each cross section are used as the sample autocorrelation coefficients. This test statistic is similar to the (Box-Pierce) Q statistic proposed by Box and Pierce and is distributed as a chi-square distribution with seventeen degrees of freedom in this case. If the null hypothesis of no autocorrelation is rejected, then we conclude that autocorrelation is present.

Three of the four consumption models posited in this study contain a lagged dependent variable. Johnston indicates that using GLS in a model with lagged dependent variables and autocorrelated errors will result in inconsistent estimates. Consistent estimates can be obtained by using an instrumental variable technique. The instruments for the lagged endogenous variable are the first and second lags of the exogenous variables. The instrumental variable technique is not needed for the relative income hypothesis model and is not needed if the error terms are not correlated.

Godfrey and Pesaran explore three tests of the non-nested hypothesis of no significant differences between the alternative econometric models. The orthodox test embeds the non-nested equations in a general specification. The J-test and the Cox test can also be used to test the non-nested hypothesis. This analysis has only one nonoverlapping variable in each consumption model. Thus, the orthodox test will have the same asymptotic power as the J-test and Cox test. Monte Carlo analysis conducted by Godfrey and Pesaran suggests that the J-test has low power in small samples. The Cox test is a paired test so it would be more difficult to apply in this case.

To conduct the orthodox test, the four consumption models are pooled. The null hypothesis for each consumption model is that the coefficients on the variables excluded from that consumption model are not significantly different from zero. If all four null hypotheses are rejected, the pooled model is used. If we fail to reject all four null hypotheses, then we conclude that there is no significant difference between the models. If we reject a subset of null hypotheses, then the models associated with the null hypotheses that we failed to reject explain consumption significantly better than the other models.

Results

The estimated consumption functions are presented in table 2. Theoretical foundations of the different models suggest that the signs of all the independent variables in table 2 should be positive. All of the variables have the expected sign. The hypothesis of no autocorrelation was rejected for each of the four models. Thus, the instrumental variable technique was used to obtain consistent estimates for all models except the relative income hypothesis model.

[3] Nominal net worth peaked in 1981 and declined from 1982 to 1986. Nominal land values in Illinois peaked in 1981 (USDA). Land values declined 48% in nominal terms and 58% in real terms between 1981 and 1986 for both the sample of farms and for Illinois as reported by USDA. Real liabilities increased by about $115,000 from 1979 to 1986.

Table 2. Estimated Consumption Functions for a Sample of Illinois Farms

Independent Variable[a]	Consumption Model: Partial Adjustment	Relative Income	Permanent Income	Life Cycle
Intercept	2,363.990	15,997.800**	3,699.310**	827.554
	(0.770)	(14.279)	(1.538)	(0.251)
C_{t-1}	0.852***		0.830***	0.865***
	(10.588)		(10.992)	(9.743)
IBD_t	0.020**			0.017*
	(2.101)			(1.446)
IBD_o		0.143***		
		(14.862)		
$IBD_t - IBD_o$		0.007*		
		(1.429)		
PI_t			0.026*	
			(1.291)	
A_t	24.912			
	(0.348)			
NW_t				0.008***
				(2.447)
Q[b]	29.398**	25.274*	30.284**	30.249**

Note: The t-ratios are in parentheses. One asterisk denotes significance at the 10% level, two asterisks denote significance at the 5% level, and three asterisks denote significance at the 1% level (one-tailed test).

[a] The independent variables are defined as: C_{t-1} is lagged real consumption, IBD_t is real disposable household income plus depreciation, IBD_o is the previous peak level of real disposable household income plus depreciation, PI_t is real permanent income, A_t is the age of the head of the household, and NW_t is real net worth.

[b] Q is a test of the null hypothesis of no autocorrelation and is distributed as a chi-square distribution with 17 degrees of freedom in this case.

The income variable, IBD_t, was significant for the partial adjustment and life cycle models. For the relative income model, the previous peak income variable IBD_o, and the short-run income effect, $IBD_t - IBD_o$, were significant. Permanent income was significant using the weighting scheme of $1/2\ IBD_t + 1/3\ IBD_{t-1} + 1/6\ IBD_{t-2}$ in the permanent income model.

Lagged consumption, C_{t-1}, was included in the partial adjustment, permanent income, and life cycle models. Not surprisingly, coefficients on lagged consumption were significant in these models. This indicates that the adjustment to fluctuating income, as well as other effects, is not instantaneous.

The age of the operator, A_t, was insignificant in the partial adjustment model, perhaps reflecting the limited range of the age of the heads of households in this sample.[4] Estimation of the life cycle model suggests that the wealth effect, as measured by NW_t, is significant.

Table 3 presents the results of the non-nested hypotheses tests. The null hypothesis for each consumption model is that the coefficients on the variables excluded from that consumption model are not significantly different from zero. The null hypothesis is rejected for the partial adjustment, relative income, and permanent income consumption models. For the life cycle consumption model, we fail to reject the null hypothesis. Thus, the orthodox test results indicate the life cycle consumption model, which includes net worth as a variable, explains consumption behavior significantly better than the other models.

The short-run and long-run marginal propensities to consume (MPC) are reported in table 4. Estimates of the short- and long-run MPCs ranged from 0.007 to 0.020 and 0.143 to 0.381, respectively, using disposable household in-

Table 3. Tests of the Non-Nested Hypotheses

Consumption Model	Orthodox Test Statistic[a]
Partial adjustment	4.592***
Relative income	4.138***
Permanent income	5.901***
Life cycle	2.570

[a] An F-test (Wald test) was used to determine if the excluded variables' coefficients were significantly different from zero. Three asterisks denote significance at the 1% level.

[4] Fifteen of the operators were between 35 to 50 years of age in 1986. The other three operators were over 50 years old.

come plus depreciation as the income measure. These estimates are lower than results from previous studies. However, the range of estimates is smaller than the range of estimates reported in previous studies. For example, Girao, Tomek, and Mount's estimates of the short-run and long-run *MPC*s ranged from −0.047 to 0.243 and from 0.112 to 0.571, respectively. The "best estimates" from Mullen, Powell, and Reece ranged from 0.13 to 0.16 and 0.19 to 0.25. However, Mullen, Powell, and Reece did not estimate the life cycle model. Without the life cycle model, estimates of the short- and long-run *MPC*s ranged from 0.007 to 0.020 and 0.143 to 0.162, respectively, in this study. Mullen, Powell, and Reece do not report a measure of income volatility. The sample of farms used in the Girao, Tomek, and Mount study had incomes that were less volatile than the incomes of the farms used in this study. Friedman suggested that individuals with a volatile income stream will have relatively lower marginal propensities to consume. The results in this study support this contention.

Table 4. Marginal Propensities to Consume for a Sample of Eighteen Illinois Farms for the 1979–86 Period

Model	Short-Run MPC	Long-Run MPC[a]
Partial adjustment	0.020	0.144
Relative income	0.007	0.143
Permanent income	0.013	0.162
Life cycle	0.017	0.381

[a] The long-run marginal propensity to consume except for the relative income model was calculated using the average real growth rate of consumption over the sample period, −0.0108, and the method used by Evans.

Robustness of the Results

The previous analysis used a relatively small sample (18 farms) to investigate farm consumption behavior over an eight-year period. The consumption behavior of a larger sample of farms could have been evaluated over a shorter time period. However, a longer time series permits more precise econometric estimates and allows use of the non-nested hypotheses tests. In this section the robustness of the results is examined by analyzing a cross section of 191 Illinois farms with data for both 1986 and 1987.[5]

Consumption in 1986 for the 191 farms averaged $28,537, while the mean disposable household income and net worth were $51,911 and $125,567, respectively. Average consumption and disposable household income plus depreciation were 11% and 7% lower and net worth was 89% higher for the 191 farms than for the smaller sample of 18 farms. The average ages of the operator and oldest child were forty-five and nine years, respectively, in 1987. The average household size was 3.5 people.

With only two years of data the permanent income model with a weighted three-year lag structure cannot be estimated. Alternatively, a weighting scheme of $1/2\ IBD_t + 1/2\ IBD_{t-1}$ is used for the permanent income model. A more serious problem is associated with estimating the previous peak income variable in the relative income model with only two years of data. This problem will affect both the short-run income measure ($IBD_t - IBD_o$) and the long-run income measure (IBD_o). Because of this, the relative income model was not estimated for the 191 farms.

The short-run and long-run marginal propensities to consume (MPCs) for the 191 farms are reported in table 5. The estimates of the short-run and long-run MPCs ranged from 0.022 to 0.039 and 0.102 to 0.132. A Wald test was conducted to determine if the short- and long-run MPCs for the partial adjustment, permanent income, and life-cycle models were significantly different than the MPCs reported in table 4. Results indicated that short-run MPCs were not significantly different, while the long-run MPCs were significantly different than those reported

Table 5. Marginal Propensities to Consume for a Sample of 191 Illinois Farms for the 1986–87 Period

Model	Short-Run MPC	Long-Run MPC[a]
Partial adjustment	0.039	0.120
Permanent income	0.022	0.132
Life cycle	0.023	0.102

[a] The long-run marginal propensity to consume except for the relative income model was calculated using the average real growth rate over the sample period, 0.0050, and the method used by Evans.

[5] Like the smaller 18 farm sample, these 191 farms are predominantly grain farms located in central Illinois. Because participation in the Illinois Farm Business-Farm Management Association is voluntary, the 191 farms do not constitute a random sample of farms in central Illinois and may not be representative.

in table 4.[6] With only two years of data it is probably not possible to obtain precise estimates of the long-run MPCs.

In summary, the results are not fragile with respect to a larger sample of farms. The short-run MPCs for the larger sample of farms were not significantly different than the short-run MPCs for the smaller sample. The significantly different long-run MPCs is probably due to the short time period used in the estimation with the larger sample.

Conclusions and Implications

This study determined the marginal propensity to consume (MPC) for eighteen Illinois predominately grain farms over the 1979–86 period. The partial adjustment, relative income, permanent income, and life cycle models of consumption were used to specify consumption functions. Results of non-nested hypotheses tests indicated the life cycle hypothesis explained consumption better than the other models. In the life cycle consumption model, lagged consumption, income, and wealth have an influence on consumption behavior. The estimates of the short-run and long-run MPCs ranged from 0.007 to 0.020 and 0.143 to 0.381, respectively.

The low MPC of farm families has important implications for firm behavior. Consumption does not react one-for-one to changes in income. A large increase in income for a particular year will result in a substantially smaller proportional increase in consumption. Thus, money is available for other uses of funds such as expansion of the firm, debt payment, or savings for retirement. Similarly, a decline in income will result in a smaller proportional decrease in consumption. During a low income year, the other uses of funds such as machinery and building purchases, savings, and principal payments would be curtailed. Farmers with low incomes in the 1980s typically reduced expenditures for inputs as well as machinery and buildings, deferred principal payments, did not expand, and tended to maintain family living expenditures. For example, farm tractor purchases and combine purchases dropped 66% and 76%, respectively, from 1979 to 1986 (Federal Reserve Bank of Chicago).

What do the low MPCs imply for researchers and policy analysts trying to model firm behavior? First, models that assume consumption is constant over time are not as ad hoc as they may seem. However, the level of family living expenditures may be much higher than is commonly assumed. Second, consumption becomes a proportionally larger use of funds during low income years. Consumption displaces equipment purchases, debt repayment, and other uses of funds when income is lower than normal. Furthermore, with recovery of the agricultural sector, until incomes exceed the nearly fixed levels of family consumption, increases in farm family income will have little effect on other farm expenditures.

[Received February 1989; final revision received June 1989.]

[6] The Wald test statistics for the short-run *MPC*s are 1.32, 1.03, and 0.10 for the partial adjustment, permanent income, and life cycle models, respectively. The critical *F*-value at the 5% level of significance is 3.90. The Wald test statistics for the long-run *MPC*s are 5.06, 3.92, and 5.30. The critical *F*-value at the 5% level of significance is 3.05 for the partial adjustment and permanent income models. The critical *F*-value at the 5% level of significance is 2.66 for the life-cycle model.

The Effect of Usage and Size on Tractor Depreciation

Gregory M. Perry, Ahmet Bayaner, and Clair J. Nixon

An econometric model was estimated to explain prices for tractors sold at auction. Tractor age, hours of use, size, and condition were statistically significant explanatory variables. Real tractor depreciation most closely approximated a sum-of-the-years digits pattern. Tractors sold at consignment and bankruptcy auctions brought a lower price than tractors sold by retiring farmers. High levels of usage did not greatly reduce tractor value, but tractors with low annual usage brought substantial premiums in the auction market.

Key words: asymmetric information, auction, Box-Cox, depreciation, tractors.

Economic depreciation of farm machinery is a significant cost of production for most farmers. Defined as the change in the value of a durable asset over a particular time period, economic depreciation is a function of (*a*) physical deterioration and obsolescence, and (*b*) changes in market supply and demand for the asset. Deterioration and obsolescence are influenced by age, use, and care of the asset. A number of studies of economic depreciation suggest depreciation rates can differ greatly among types, sizes, and manufacturers of farm equipment (Peacock and Brake; Leatham and Baker; Perry, Glyer, and Musser; McNeill).

In most of the above-cited studies of economic depreciation, age is assumed to represent the effects of deterioration and obsolescence on equipment values. Although usage levels and tractor size were assumed when developing equipment replacement models, the effect of usage on depreciation was not considered. This paper focuses on the effects of usage, care, and size on tractor depreciation. Significant differences between this and previous studies include use of actual market data and a flexible functional form that allows annual depreciation rates over time to more fully reflect patterns in the data.

Model Development

The value of a durable asset is the net present value of the stream of expected net returns over its remaining life. Durable capital assets have finite productive lives and are subject to deterioration and obsolescence. Physical deterioration largely reflects the effects of use and care on the asset.[1]

As Keynes noted, the usage level "constitutes one of the links between the present and the future. For in deciding his scale of production an entrepreneur has to exercise a choice between using up his equipment now and preserving it to be used later on" (pp. 69–70). Presumably the entrepreneur will use up equipment in the present if it is more profitable to do so. However, higher levels of usage can be expected to shorten the life of a durable asset, thereby reducing the stream of future returns and the asset's current market value.

Care can moderate the effects of usage. By care, we mean not only the maintenance and repairs regularly performed by the asset owner but also the manner in which the asset is treated.[2] Care can also be considered an economic decision (Parks, Kim). Low levels of care will generally result in higher rates of depreciation.

[1] A durable asset that is never used might also deteriorate over time. However, few capital assets will actually be left idle for long because of high opportunity costs. In most cases, therefore, the major portion of physical deterioration is a function of usage and care.

[2] For example, equipment parked under cover during the winter will probably last longer and maintain a higher market value than equipment left out in the elements.

Obsolescence reflects the rate of technological change over time. If deterioration is fully reflected by usage and care, changes in equipment value with age (at constant usage and care levels) should reflect the effects of obsolescence on asset depreciation. Changes in value over time may also reflect the cost of parts and services provided by the manufacturer.[3] In general, then, a change in equipment age will reduce equipment value.

Most previous estimates of depreciation have focused on specific types of durable assets (such as tractors). These data are often pooled across a number of attributes. Perhaps the most significant attributes for tractors are manufacturer and tractor size (see Reid and Bradford 1983 or Leatham and Baker). The manufacturer embodies a particular level of quality and technology. Consequently, the effects of age and usage could vary among manufacturers.

Larger tractors may experience more intense use than smaller tractors, resulting in more rapid deterioration rates. Obsolescence may also vary across tractor sizes. The relatively larger market for smaller tractors, for example, may cause manufacturers to invest more resources in developing technological advancements for these tractors.

Changing supply and demand conditions also may influence tractor values. Peacock and Brake suggested that net farm income, index of prices received by farmers, index of labor costs, and crop acreage could represent macroeconomic conditions for tractors. Real after-tax interest rates (Hall) and the total stock of tractors might be considered as well.

Data

Studies of depreciation for U.S. tractors have generally relied on dealer resale prices published semi-annually by the National Farm Power and Equipment Dealers Association (NFPEDA). Their *Official Guide* contains summaries of prices received by dealers for used farm tractors of various manufacturers. However, use of equipment dealer sales data in studying depreciation might introduce some bias, since prices may reflect the value of warranties, financing options, and trade-ins. The effects of usage and maintenance are not explicitly reported or estimated by the NFPEDA. Furthermore, a constant depreciation rate is assumed when calculating resale prices for the same model tractor manufactured in different years.

Previous research has relied on average "as-is" prices from the *Official Guide* in their estimation of depreciation patterns. The "as-is" price is calculated by subtracting a reconditioning cost from the dealer's resale price, then reducing the remainder by a percentage of dealer markup. Close inspection suggests that, although prices are reported in nominal terms, a particular tractor model's reconditioning cost is often the same year after year.[4] In addition, the dealer markup is always 20% (pre-1979 tractors) or 15% (1979–present), regardless of the tractor's age, condition or manufacturer. These methods raise questions about the accuracy of NFPEDA data in establishing farm-level tractor values.

An alternative to the *Official Guide* is auction data, which have been available for many years in *Implement and Tractor* (Farm Press Publications, Inc.). Since 1984, Hot Line, Inc. has published the *Farm Equipment Guide,* which contains a monthly series of auction prices paid for farm equipment in different parts of the United States. These transactions are reported by auctioneers and often include price, manufacturer, name, model, year manufactured, condition, hours of use, auction location, auction date, and other descriptive information. This data set was used as the basis for the econometric analysis.

An incomplete data series was available for 1984, so the analysis was limited to 1985 through 1988. The data set was further limited to tractors with greater than eighty horsepower, assuming they are generally used by larger farming operations. Smaller tractors are mostly used by hobby farmers, smaller production-intensive operations (such as orchards) and large operations in secondary uses.

Most previous econometric estimates of tractor depreciation have used remaining value (RV) as the dependent variable. RV is the current price divided by the original purchase price (in current dollars). The RV approach allows prices for tractors of different sizes and attributes to be grouped together in a common data set, thereby providing sufficient degrees of freedom for estimation purposes. List price (as reported in the *Official Guide*) was used as a proxy for sale price in RV calculations because original sale price

[3] It may be difficult, for example, to obtain parts for older tractors, causing their cost to increase.

[4] For example, the reconditioning cost for a 1973 IH Model 1066 tractor was $650 for the 1974–87 period.

was not available. The list price was adjusted for options (e.g., cab, air conditioning, etc.) if the transaction indicated they were present. An index was created to account for changes in the list price level, using average prices paid for two-wheel drive, 110–129 horsepower tractors (USDA). All prices reported in the auction data and their corresponding list prices were converted to 1982 dollars using this index.[5]

The data set was also limited to the seven manufacturers that dominate this portion of the tractor market (designated as companies A, C, D, F, I, M, and W). Tractors manufactured before 1971 were excluded because data for list prices were difficult to obtain. The resulting data set contained 1,030 observations. The data are summarized by manufacturer in table 1.

The RV model can be expressed as

$$RV = f(Usage, Care, Age, Size, Manufacturer, Macroeconomic\ Variables).$$

Tractor hours of use is perhaps the best measure of usage for tractors. Because total tractor hours are highly correlated with tractor age, the usage variable was represented as an annual value (total hours/age). Age was used to account for the effects of obsolescence on *RV*.[6]

No records of care were available from the auction data. However, the auctioneers did report their subjective assessment of each tractor's condition on a scale of 1 (excellent) to four (poor). This condition variable was used as a proxy for care in the model. Tractors in good condition (2) represented the majority (56%) of all observations.

Tractor size was represented by PTO horsepower. An interaction term between horsepower and usage accounted for different intensities of use in larger versus small tractors. A negative sign was hypothesized, suggesting higher usage intensity for larger tractors. An interaction term between age and horsepower reflected different rates of technological obsolescence for different tractor sizes. A positive sign was hypothesized.

Dummy variables represented the seven manufacturers. A set of manufacturer-age interaction terms accounted for any differences in the rate of obsolescence among companies. Manufacturer-usage interaction terms were also included to represent differences in tractor quality among manufacturers.

All macroeconomic variables suggested in the previous section were considered in the analysis. However, because data on total tractor stocks were incomplete, this variable was omitted. The price indexes for labor, prices received by farmers, and total crop acreage were highly correlated with one another and with real net farm income (lagged one year, 1982 price level). Consequently, only real net farm income and real after-tax interest rates were retained in the model.[7]

The auction sales reported in the *Farm Equipment Guide* represent all parts of the United States. Differences in price might occur among regions because of transportation costs and supply/demand relationships. Thus, the United States was divided into six regions: (*a*) Far West, (*b*) Northern Great Plains, (*c*) Southern Great Plains, (*d*) Western Corn Belt, (*e*) Eastern Corn Belt and Northeast, and (*f*) Southeast.

The observations were concentrated in the Western Corn Belt (47%). Each region was represented by a dummy variable, with the Western Corn Belt dummy omitted for estimation pur-

[5] An alternative index could have been created using sale prices of 170–240 horsepower 4-wheel drive tractors. The 110–129 horsepower price series was used because almost 70% of all observations were for tractors with less than 150 horsepower.

[6] Because usage is expressed as an annual rate, it probably does not fully reflect the effects of total usage on *RV*. Consequently, the age variable may capture some of the effects of usage. However, the correlation between total usage and annual usage is .75, suggesting that annual usage probably reflects most of the impact of usage on depreciation.

[7] The after-tax discount rate was calculated using average interest rates charged farmers for machinery loans (Board of Governors of the Federal Reserve System) multiplied by one minus the estimated marginal tax rate (federal and state), then reduced by the implicit GNP deflator (Council of Economic Advisors).

Table 1. Averages of Data and Number of Observations by Manufacturer

	Number of Observations	*RV*	Age (years)	PTO Horsepower	Annual Usage	Condition
Company *A*	64	0.207	8.58	143	268	1.69
Company *C*	90	0.255	7.91	152	290	1.73
Company *F*	17	0.235	10.22	105	308	1.93
Company *D*	512	0.362	8.53	135	361	1.80
Company *I*	277	0.228	8.97	135	309	1.85
Company *M*	34	0.202	10.5	127	264	1.94
Company *W*	26	0.200	10.5	123	222	1.85

poses. Regional parameters were expected to have positive signs because most U.S. tractor manufacturing facilities are located in or near the Western Corn Belt region.

Four types of auctions were represented in the data. Farmers retiring from agriculture (including estate sales), represented 62% of all observations reporting a specific auction type.[8] Also included in the data set were consignment sales (26%), bankruptcies (9%), and dealer closeouts (3%).

Ackerloff argues that used assets will sell at a discount because of asymmetric information about asset quality between buyer and seller. That is, the seller may be disposing of a "lemon" but does not share this information with potential buyers. Consequently, buyers discount their bid price to account for the higher probability of purchasing an inferior good. The consignment and dealer closeout auctions may experience such bias. In contrast, farmer retirement and bankruptcy auctions should generate higher bid prices because the sale is not motivated by liquidating a "lemon."[9] To account for auction type, dummy variables represented each type of auction. The dummy for farm retirement auctions was dropped for estimation purposes. Negative and significant coefficients for consignment and dealer closeout auctions were hypothesized, while an insignificant coefficient for bankruptcy auctions was expected.

Functional forms used in previous econometric estimates of tractor depreciation include linear (Peacock and Brake), exponential (McNeill, Leatham and Baker), and Cobb-Douglas (Reid and Bradford 1983). Choice of a functional form can significantly influence the depreciation pattern. The exponential form, for example, results in a constant depreciation rate. Hulten and Wykoff (1981) suggest use of the Box-Cox flexible functional form when estimating depreciation models because it allows the data to determine the depreciation rate and pattern over time.

The generalized Box-Cox model can be written as

$$\frac{Y^{\lambda}-1}{\lambda} = \alpha_o + \sum_{i=1}^{k} \beta_i \frac{X_i^{\gamma i}-1}{\gamma i} + \epsilon,$$

where λ is the transformation on the dependent variable y, β_i is the regular coefficient for the ith independent variable (X_i), and γ_i is the transformation coefficient for X_i. The Box-Cox can imitate a number of depreciation patterns for durable assets. Assuming X_1 is age, these patterns include linear ($\lambda = 1$, $\gamma_1 = 1$), geometric ($\lambda = 0$, $\gamma_1 = 1$), sum-of-the-year's digits ($\lambda = 0.5$, $\gamma_1 = 1$), and Cobb-Douglas ($\lambda = 0$, $\gamma_1 = 0$). Depreciation rates are, in general, declining over time if $\lambda < 0$ and $\gamma_1 \leq 1$, with increasing rates occurring when $\lambda \geq 0$ and $\gamma_1 > 1$.

The form of the estimated model is

$$\begin{aligned} RV^* = &\sum_{i=1}^{7} \alpha_i M_i + \sum_{i=1}^{7} \beta_i M_i A^* + \sum_{i=8}^{14} \beta_i M_i HPY^* \\ &+ \beta_{15} A^* HWP^* + \beta_{16} HPY^* HWP^* \\ &+ \beta_{17} HWP^* + \beta_{18} NFI + \beta_{19} I + \beta_{20} C \\ &+ \sum_{j=1}^{5} \beta_{20+j} R_j + \sum_{k=1}^{3} \beta_{25+k} T_k, \end{aligned}$$

where

$$RV^* = \frac{RV^{\lambda}-1}{\lambda},\ A^* = \frac{Age^{\theta}-1}{\theta},$$

$$HPY^* = \frac{(Average\ Hours)^{\gamma}-1}{\gamma},$$

$$HWP = \frac{Horsepower^{\phi}-1}{\phi},$$

NFI is real national net farm income (in 1982 \$bill.), I is real after-tax discount rate, C is condition, M_i is dummy variable equal to 1 for the ith manufacturer, R_j is dummy variable equal to 1 for the jth region, and T_k is dummy variable, equal to 1 for the kth auction type. The model was estimated using the SHAZAM econometrics package. Because of the nature of the model, a manual grid search technique was needed to estimate the θ, γ, and ϕ values.

Results and Analysis

The econometric results are reported in table 2. The $\bar{R}^2$ statistic was high given the number of observations and diverse nature of the data. The transformation on RV suggests that a change in any independent nontransformed variable causes a smaller change in RV as RV declines. Thus, real net farm income has less absolute influence on real tractor price as the price declines. The transformations for RV and age suggest the real rate of technological obsolescence most closely exhibited a sum-of-the-years digits pattern.

[8] Auction type was not reported until mid-1986. This percentage was calculated only for data that indicated an auction type.

[9] The condition variable accounts for tractor care; thus, lack of care provided by farmers in some situations (such as bankruptcy) should already be captured in this variable.

[a] Asterisk indicates significant at the 95% confidence level.

The company intercept values determine the initial depreciation when a new tractor is sold. The results suggest tractors from companies *A*, *C*, *I*, and *M* experience about the same initial drop in value. Tractors from companies *D* and *W* experience a smaller initial decline. The company *F* intercept is much lower than the other values, suggesting little initial decline in values.

The coefficients for usage were negative and significant for all companies. The company *D* coefficient for usage was much lower, suggesting that their tractors had the highest level of perceived quality during the 1971–88 time period. In contrast, tractors from companies *F* and *W* exhibited large declines in value as annual usage increased.

The coefficients for age were also negative for all companies. Again, changes in age had

the least influence on company *D* tractors and the largest influence on tractors from companies *F* and *W*. These results suggest tractors in the 80+ horsepower range can be grouped into three different categories based on the effects of usage and age. The first is the average group, consisting of tractors manufactured by companies *A*, *C*, *I*, and *M*. The second group, consisting of company *D*, maintains an *RV* above that of the average group at all age and usage levels. The third group, consisting of companies *F* and *W*, have a higher initial value than the average group but depreciate much more rapidly with time and use.

In general, the effects of usage on depreciation were much greater at lower usage levels. This point is illustrated in figure 1.[10] A one-year-old tractor, for example, may have an *RV* of almost 70% at 50 hours of annual usage or 52% at 1,000 hours annual use. The effect of usage on *RV* declines, however, as *RV* becomes smaller.

[10] In calculating figures 2 and 3, it was assumed (unless otherwise noted) that real net farm income was $33 billion (1986 value, 1982 dollars), average real net farm income was $4,665 (1984–86 average 1967 dollars), real after-tax interest rate was 5.5% and that the tractor was a 130-horsepower model manufactured by Company D, in good condition, 300 hours of annual use, and sold in the Western Corn Belt region at a farmer retirement auction.

The horsepower and usage-horsepower interaction coefficients were both insignificant. The age-horsepower interaction coefficient was significant, but the coefficient sign was opposite of that hypothesized. The effect of horsepower on depreciation patterns (where usage and care are held constant) is illustrated in figure 2. Larger tractors had a higher initial *RV* but depreciated (in real terms) much more rapidly than the smaller tractors.

Two alternative hypotheses are posited to explain the more rapid increase in depreciation rates in larger tractors. First, technological change may have proceeded more rapidly in larger tractors. In the early and mid-1970s, large tractors were a relatively new innovation, whereas 100-horsepower, two-wheel drive tractors had been available for more than a decade. The technological inefficiencies embedded into the first generation of larger tractors may have caused heavy discounts in current used tractor markets.

A second hypothesis involves performance reliability. Larger tractors presumably are purchased by farmers with larger operations or limited time for field operations. Downtime costs probably are higher for these farmers. As a tractor ages it generally becomes less reliable, thus diminishing its market value. Smaller tractors,

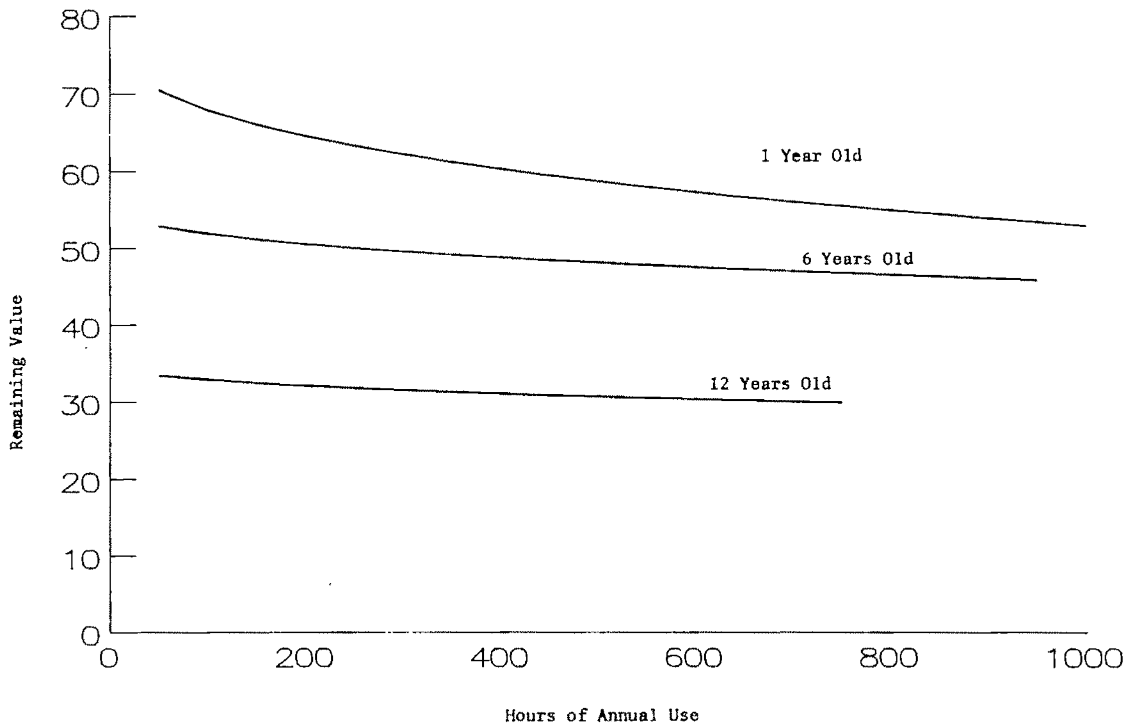

Figure 1. Remaining value for 130 HWP tractor at different use and age levels

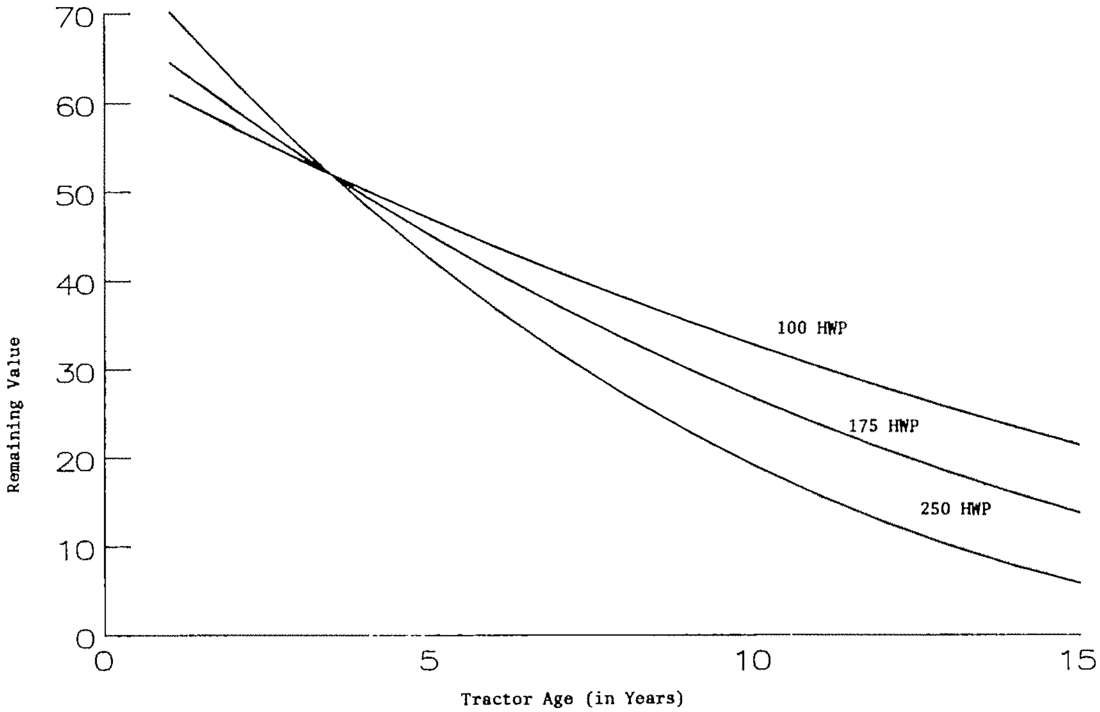

Figure 2. Remaining value by year for different tractor sizes

on the other hand, often perform less critical tasks or are used in smaller operations that are less constrained by tractor capital. Consequently, reliability is less important with smaller tractors and would have less impact on their prices.

Real net farm income had a positive impact on *RV*, consistent with the initial hypothesis. The regional dummy results suggest that tractor prices were lowest in the Southeast and increased as one moved west and north.

The results verified the hypothesis that prices at farmer retirement auctions were higher than consignment and dealer closeout sales, with the difference between consignment and farmer retirement auctions being statistically significant. On the other hand, the bankruptcy dummy coefficient was negative (and significant). Discussions with auctioneers suggest a more complicated auction exists when bankruptcy is involved.

A liquidation bankruptcy auction (Chapter 7) functions much like a retirement auction. In contrast, it is common at a reorganization bankruptcy sale (Chapter 11) for the farmer to attend the auction of his own equipment and bid on those pieces he wants. His neighbors, who often constitute the majority of potential buyers, will not bid against him, out of sympathy or respect. Consequently, the farmer will buy the equipment he wants at a relatively low price.

The results support Ackerloff's argument that uncertainty about why a piece of equipment is being sold may cause buyers to bid less than the equipment's perceived value. The asymmetric information argument does not, however, totally explain why tractors drop in value so rapidly when first purchased. For example, a new 130-horsepower tractor with no hours on it would have an *RV* of 90.5 if sold at a farmer retirement auction and 86.0 if sold on consignment.[11] The same tractor sold after 100 hours of use would generate an *RV* of 78.8 if sold in a farmer retirement auction. Perhaps the expiration of free dealer services (such as those in warranties) may account for this large drop in value.

Figure 3 provides a comparison of annual depreciation rates over a ten-year period for this model versus four other models.[12] The other models were estimated and (or) reported by Reid and Bradford (RB), Leatham and Baker (LB), Peacock and Brake (PB) and the *Agricultural Engineering Yearbook* (ASAE). Two versions

[11] An *RV* of 90.5 for a new tractor suggests list prices may be higher than actual sale prices.

[12] The depreciation rate is calculated as

$$Rate = \frac{|RV_{t-1} - RV_t|}{RV_{t-1}}.$$

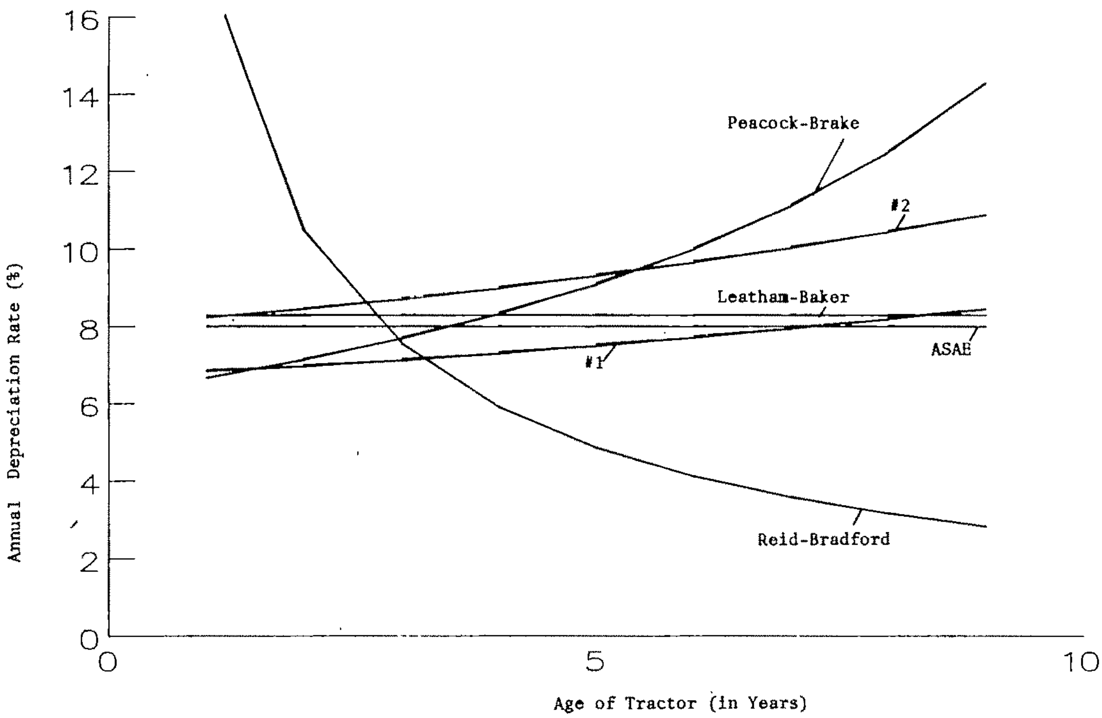

Figure 3. Annual depreciation rates for different remaining value models for tractors

of the auction data model are given in the figure. The base case (designated as number one) presumes annual usage and condition remain constant during the ten-year period. An alternative situation (designated as number two) also has a constant usage level, but allows condition to begin at 1.0 and increase by 0.2 units per year.

Both versions of the model exhibited depreciation patterns that were in between the ASAE-LB models and the PB model. This pattern is consistent with the flexible functional form estimated for the data. The RB model exhibited a substantially different depreciation pattern, due in part to their choice of functional form.

A decline in condition accelerated the depreciation rate by about 2% per year. Condition generally declines over time, so number two may more correctly reflect annual depreciation rates. Offsetting a decline in condition, however, would be a decline in the annual usage level. Average usage remained at about the same level in the data during the first ten years of tractor life and then declined.[13]

[13] Usage patterns in the data make it difficult to make general statements about how individual usage patterns vary over a tractor's life. A more or less level usage pattern in the data suggests usage does decline over time because crop acreage has been on a steady decline during most of this decade.

Concluding Comments

This paper focused on the influence of usage and size on tractor values. A remaining value equation was estimated for tractors sold in auctions during the 1985–88 period. Both usage and horsepower were significant variables in explaining changes in tractor price. Differences in tractor prices were also evident between companies, regions of the United States, and types of auctions. Above-average levels of usage did not result in large discounts in tractor price, but low-average usage did generate substantial premiums. Larger tractors depreciated more rapidly than their smaller counterparts. The type of auction sale was also influential on auction price.

A logical next step in this analysis would be to use the *RV* equation in identifying optimal equipment replacement patterns for tractors. Given the effect of different *RV* equations on optimal replacement and the differences in depreciation patterns demonstrated in figure 3, one might expect that this new *RV* model will identify replacement patterns that differ from those identified by other researchers.

A Prospective Assessment of the Impacts of Bovine Somatotropin: A Case Study of Wisconsin

Bruce W. Marion and Robert L. Wills

The predicted effects of bST on aggregate supply, milk price, and farm structure is extremely sensitive to several key assumptions: the impact of bST on production per cow, cost of bST to farmers, returns required by farmers to adopt bST, price of milk when bST is introduced, speed and extent of adoption. A case study of Wisconsin dairy farms indicates that the overall economic impact of bST will be much less than most other studies have predicted. The projected effects, however, are similar to Cochrane's treadmill theory, albeit less severe than predicted by earlier estimates.

Key words: biotechnology, bST, *ex ante* assessment, new technology, socioeconomic impact.

Prospective assessments of new technologies are difficult and need to be judged by different standards than after-the-fact assessments (Fishel). Benefits and costs of future technologies are uncertain. Moreover, the speed and extent of adoption are unknown. However, social scientists are increasingly asked to make social and economic assessments of technologies prior to their commercial introduction. Although such assessments may require wide confidence intervals, they still can provide useful insights to policy makers, potential adopters, and interested parties (for a different approach, see Lemieux and Wohlgenant). A well-developed model can be used to examine the sensitivity of results to various assumptions and can be updated as more information becomes available.

Of the many biotechnology products potentially affecting agriculture, probably none has received greater attention than bovine Somatotropin (bST). Prospective economic assessments of the impacts of bST can focus on individual farms, on aggregate prices and quantities, and measures of economic welfare. The 1987 study by the U.S. Department of Agriculture's Economic Research Service (Fallert et al.) is the most ambitious effort to model both the micro and macro impacts of bST. The USDA linked Westcott's simulation model of the dairy industry to farm-level simulation models of representative dairy farms in different regions. While the results of this study are of considerable interest, they are sensitive to assumptions concerning (*a*) the production response to bST; (*b*) the returns required by farmers to adopt bST; (*c*) the price that farmers will have to pay for bST; (*d*) the price of milk when bST is introduced; and (*e*) the speed and extent of adoption.

Other studies have provided prospective assessments of the economic impact of bST using different sets of assumptions (Kalter et al.; Boehlje, Cole, and English; Magrath and Tauer; Kalter and Milligan; Yonker, Knutson, and Richardson; Butler and Carter; Marion, Wills, and Butler). The research reported here examines the impact of varying the assumptions for the above five factors, using Wisconsin dairy farms as a case study.

Farm Decision Model

Most previous analyses of the farm level profitability of bST have used simulation models of representative dairy farms. A similar but more transparent farm enterprise model is employed in this study to determine the economic feasi-

Bruce W. Marion and Robert L. Wills are a professor and an associate research scientist, respectively, Department of Agricultural Economics, University of Wisconsin.

The assistance of Edward Jesse, Robert Kalter, and an anonymous reviewer are gratefully acknowledged.

bility of bST by comparing incremental revenues and incremental costs. Incremental revenue and costs were defined as:

incremental revenue from bST = % production response to bST * original production per cow * milk price

incremental costs plus returns to management = cost of bST + increased feed costs + increased hauling costs + increase in other variable costs + required return to management.

For some variables, a wide range of values is plausible. Because these variables drive the rest of the analysis and are the major reason why the results differ from previous analyses, they warrant comment.

Impact of bST on Production Per Cow

A critical question is whether bST will provide a proportional (e.g., 10%) or constant (e.g., 8 lbs.) increase in milk production, or a partly constant and partly proportional increase. Fallert et al. assumed an 8.4-pound increase per cow per day regardless of production per cow, whereas Kalter et al. examined proportional responses ranging from 6.4% to 25.6% per year. If a constant increase is assumed, bST tends to be economically feasible for all cows (and herds) or for none. If a proportional response is assumed, bST may be economically feasible on high producing cows but not on low producing cows.

Research by dairy scientists presents a mixed picture. Given the same level of management, most of the research points toward a constant response from cows of differing genetic capability. However, much of the difference in production per cow of commercial dairy farms within a state or region is attributable to differences in management. And there is a strong consensus that poor management will severely restrain the production response to bST.[1] Thus, to the extent that production per cow reflects the level of management, the response to bST is likely to be greater in high-producing herds than in low-producing herds.

The level of response under field conditions is also uncertain. Recent research suggests a daily increase in production of 17% to 25% for well-fed and well-managed cows. This translates to a 10.5% to 15.5% increase in annual production because bST is not administered until about the ninetieth day of lactation. Under field conditions the response to bST ranges from zero for poorly managed herds to results comparable to experimental results for very well-managed herds. Fallert et al. estimated that the response under field conditions would average 25% less than under experimental conditions.

Some evidence exists that first calf heifers may respond less than older cows (current research by University of Wisconsin dairy scientists), while other research shows little difference in response. Uncertainties also exist about the response rate to bST in the second, third, or later years of administering bST. In short, much remains unknown about the production effects of bST. Given these uncertainties, sensitivity analysis is appropriate. In the research reported here, we examine three levels of proportional responses (9%, 12%, and 15%), a response that is partly constant and partly proportional (900 lbs. + 6% of base production), and a totally constant response (1,800 lbs./year).

Cost of bST to Farmers

Most studies have either ignored bST cost, assumed a certain price, or determined bST price as a residual. Lesser, Magrath, and Kalter used a bST price of 17¢ per cow per day in the fictional ad sent to New York farmers to determine their attitudes toward adoption. Fallert et al. assumed that farmers will require a return to management that is twice the cost of the drug in order to use bST. With an 8.4 pounds per cow per day response to bST and 1986 price levels, they found that representative U.S. dairy farmers could pay 24¢ per cow per day and still achieve the required two for one return. Several studies assume that bST will be sufficiently profitable for farmers so that the price of bST will not con-

[1] This section relies on conversations with dairy scientists Dale Bauman, Cornell University, and Dave Combs, University of Wisconsin-Madison. Bauman, one of the leading researchers of bST, believes the response to bST will be at least partly proportional to base production per cow. However, we also acknowledge the point made by one of our reviewers: "The assumption of differences in production per cow being attributable to differences in management might hold within a state but might not hold across states and regions where such factors as quality of forage and weather may be strong factors."

strain its adoption. This assumption may stem, in part, from estimates that the cost of producing bST will be 8.5¢ to 18.6¢ per daily dose (Kalter et al.) and assumptions that bST will be priced near its cost of production. Improvements in technology since Kalter's study have dropped expected bST production costs even further to 5¢ or less per daily dose.

However, the cost of producing bST may have little bearing on the price charged to farmers. The costs of marketing bST could dwarf production costs. In addition, bST manufacturers have substantial research and development sunk costs on which they hope to realize a return. Thus, bST manufacturers will have a strong financial incentive to price bST substantially above production costs.

The likely structure of the industry will allow some form of price leadership and/or coordinated pricing. Only four pharmaceutical companies are currently in the worldwide race to market bST. Two of these have a significant lead. And, large economies of scale in the production of bST indicate that entry barriers will be high. Some bST manufacturers expect to serve the world market from a single plant. Although the initial pricing strategies of these companies are difficult to predict, the high degree of oligopolistic interdependence will encourage some type of coordinated pricing.

Below, the manufacturers' profit-maximizing prices are calculated under different assumptions. In the sensitivity analysis, bST prices are allowed to range from 25¢ to 40¢ per dose.

Returns to Management Required by Farmers to Adopt bST

Most studies have not incorporated a threshold return to farmers who adopt bST as a payment for management and risk. However, farmers are unlikely to adopt bST unless at the time of adoption, they perceive an acceptable return after costs for their management and risk. Pharmaceutical companies estimate that "farmers will not likely adopt bST unless they can obtain a $2 net return for each $1 in bST purchase cost" (Fallert et al., p. 8). The logic of this estimate is questionable. Since bST will be a variable cost of production, not a capital investment, we see no reason why the net returns required by farmers for adopting bST should vary proportionally with the price of bST.

Of those responding to a survey in mid-1987 of Wisconsin dairy farmers, 36% said they would require 50¢ or less profit per cow per day of bST use, 35% would need $.51 to $1.00 per cow per day of bST use, and 29% would require over $1.00 per cow per day of bST use (Nowak and Barnes). Given the paucity of farmers' information about bST at the time of the survey, their responses are at best a rough estimate of the returns required for adoption.

These daily farmer returns can be translated into annual returns. If bST is administered for 215 days, annual returns to an owner of a fifty-cow herd corresponding to 20¢, 30¢, 40¢, and 50¢ return per cow per day are:

Return/Cow/Day of bST Use	Annual Return in 50 Cow Herd
$.20	$2,150.00
.30	3,225.00
.40	4,300.00
.50	5,375.00

If administering bST is relatively easy, as appears likely, and if the management requirements are not too high—a point on which we have little knowledge—an additional $2,000–$4,000 may be a reasonable incentive to adopt bST. In this analysis, farm returns range from 20¢ to 40¢ per cow per day. Manufacturers of bST will have strong incentives to make bST as easy to use and manage as possible. Because at least some of the management changes needed to effectively use bST will involve front-end investments in human capital or management systems, operators of small herds may require a higher return per cow per day to adopt bST than operators of large herds.

Milk Prices

Milk prices have dropped substantially in recent years and may drop even further by the time bST is introduced in late 1989 or in 1990. Whereas Kalter et al. used an all-milk price of $12.69 per hundredweight (cwt.) and Fallert et al. used an initial price of $12.52 in estimating bST profitability, Wisconsin dairy economists expect the Wisconsin all-milk price will be approximately $11.00 per hundredweight by 1990. In this analysis, we use a milk price of $11.00 or allow prices to range from $10.00 to $11.50 per hundredweight.

Increase in Feed Costs

Higher producing cows require more feed. The increase in feed costs required per hundredweight increase in milk production from bST

appears to be similar to the general relationship between feed costs and milk production. We use two linear equations to estimate feed costs, both drawn from Wisconsin Farm Enterprise Budgets (Luening et al.): (*a*) annual feed cost per cow = $201.38 + .0289 pounds of milk per year; and (*b*) annual feed cost per cow = $274.00 + .034 pounds of milk per year.[2]

Equation (*a*) has "typical" hay and concentrate prices and is used in most of our calculations. Equation (*b*) reflects higher feed costs and is used for sensitivity analysis.

Increase in Hauling and Other Variable Costs

Increased milk production from bST will likely increase the variable costs of milk hauling, farm labor, power, breeding, and veterinary services. The average cost to farmers of hauling milk in Wisconsin is currently about 20¢ per hundredweight. There is no research on the additional labor, veterinary, breeding, and power expenses associated with bST usage. Wisconsin Farm Enterprise Budgets (Luening et al.) indicate that as annual production per cow increases 100 pounds, these expenses increase 67¢. Based upon these figures, hauling and other variable costs are assumed to increase by 87¢ per hundredweight for milk increases resulting from bST. We also examine the effect of a lower increase in variable costs (.20 + .335 = .54/cwt.) The example in table 1 shows how the farm decision model works.

Given the assumed values, incremental revenues exceed incremental costs plus the return to management. BST would be economically feasible on cows producing somewhat less than 16,000 pounds of milk per year. The break-even production per cow changes significantly for different responses to bST, different milk prices and different bST prices plus farm return (table 2).

Table 1. Illustration of Farm Decision Model for bST, Wisconsin, 1990

Incremental Revenue Assumptions:	
Milk price in $/cwt.	$11.00
Annual production per cow without bST	16,000 lbs.
% annual response to bST	12%
Calculations:	
Incremental milk production:	
160.0 * .12 =	19.2 cwt.
Incremental revenue:	
19.2 cwt. * $11.00 =	$211.20
Incremental Cost Assumptions:	
bST price/cow/day	.30
Increased returns to farm mgt./cow/day	.30
Milk hauling costs/cwt.	.20
Labor, power, breeding, & vet. costs/cwt.	.67
Feed cost increase per cwt.	2.89
Calculations:	
bST price: $.30 * 215 days use/cow	64.50
Returns to mgt.: $.30 * 215 days	64.50
Milk hauling: $.20 * 19.2 cwt.	3.84
Other variable costs: $.67 * 19.2 cwt.	12.86
Increased feed costs: 2.89 * 19.2 cwt.	55.49
Total incremental costs	$201.19

Distribution of Wisconsin Herds by Average Production Per Cow

If the response to bST is at least partially proportional to the production per cow, then the distribution of cows by level of output becomes important in estimating the potential use of bST. Data on the distribution of Wisconsin herds by level of production are from a survey of 1,163 herds (63,164 cows) conducted by the Wisconsin Agricultural Statistics Services (WASS) in January 1989.

The monthly sample distribution was expanded to derive a population distribution for Wisconsin dairy cows.[3] This estimated distribution of cows by level of production is used in the following sections to calculate the number of cows on which bST will be economically feasible under various conditions, and the increase in state milk production that may occur as a result of bST.

Potential Demand for bST

The impact of bST on state and national milk production depends upon the extent and speed of its adoption and the production response to bST. Several other studies have concluded that bST will be widely and quickly adopted, at least in part because they have assumed it will be

[2] Fallert et al. used the following equation to estimate feed costs in the Lake States:

Feed costs = $156.18 + .0271 lbs. of milk/year.

For a cow producing 16,000 lbs. of milk, feed costs estimated by Fallert et al. are $75 less than Luening et al. The forage costs estimated by Fallert et al. appear to be substantially underestimated.

[3] Annual sample 1989 milk production was calculated by dividing January 1989 values by .0813, the average proportion of annual milk production accounted for by January milk production for 1977–86. The percent of cows in each production category was applied to the total January 1989 Wisconsin dairy cow inventory of 1,730,000 to derive state values.

Table 2. Production per Cow at Which bST Use Is Feasible Under Different Economic Conditions

11.00	All cows	All cows	None
11.50	All cows	All cows	None

profitable on most cows and for most farmers. Lesser, Magrath, and Kalter estimated that bST would be used on 63% to 85% of New York cows within three years of commercialization, based upon a survey of 173 farmers in 1984. Nowak and Barnes indicated 13% of Wisconsin's dairy farmers would be early adopters of bST, 31% were unlikely to adopt, and the remaining 56% would fall in-between, based upon a survey of 270 farmers in 1987. A major limitation of these surveys is that farmers were asked to respond to a hypothetical set of facts that may or may not exist when bST is introduced.

In our analysis, we first examine the extent to which bST is economically feasible for Wisconsin cows under various assumptions. Using the incremental revenue-cost model and the distribution of Wisconsin herds by production level, we estimated the potential demand for bST. Table 3 presents two bST responses: (*a*) a 12% proportional response and (*b*) a partly fixed (900 lbs./year) and partly proportional (6%) response. In the example, the Wisconsin all-milk price is $11.00 per hundredweight and returns to management are 20¢, 30¢, or 40¢ per cow per day. The price of bST is varied from 20¢ to 50¢ per daily dose.

In order to estimate the contribution to manufacturer development costs and profits, we assume that the production and marketing costs of

.20	.40	1,140,969	1,222,669	114,097	122,267

Note: Assumptions—Wisconsin all-milk price = $11.00 per cwt.

bST manufacturers will be 10¢ per daily dose. Increasing or decreasing the cost of bST does not alter the profit-maximizing price shown in table 3.

The joint profit-maximizing price for manufacturers ranges from 25¢ to 40¢ per daily dose under the conditions assumed in table 3. Thus, if there is sufficient discipline among bST manufacturers to achieve a joint profit-maximizing equilibrium, the equilibrium price will likely fall in that range. If one or more companies choose a low price strategy in hopes of developing a dominant market share, bST could be priced much closer to production costs, at least for a while.

Small changes in either bST price or farm returns substantially change the number of Wisconsin cows on which bST is feasible and the contribution to manufacturer profits. In much of the analysis that follows, bST price and farm returns are combined to reflect the trade-off shown in table 3. Manufacturer profits in Wisconsin are maximized when the combined value of bST price and farm return is in the range of 50¢ to 70¢ per cow per day.

Sensitivity of Results

The previous sections have provided some indication of the effects of varying the assumed values of the four key variables: production response to bST, milk price, bST price and the return required by farmers to adopt bST. Figures 1 and 2 are analogous to potential demand curves for bST under different economic conditions. Figure 1 holds milk price at $11.00 per hundredweight and examines the effects of four bST response rates on the number of Wisconsin cows on which bST is economically feasible. Figure 2 assumes a 12% annual response to bST and examines the effects of three milk prices.

We are particularly interested in the potential demand for bST when the price of bST plus farm returns is between 50¢ and 70¢ per cow per day. In that range, the economic feasibility of bST is very sensitive to the values of key variables.

The sensitivity of the results to changes in feed and other variable costs also was examined. The impact of varying these two costs is shown be-

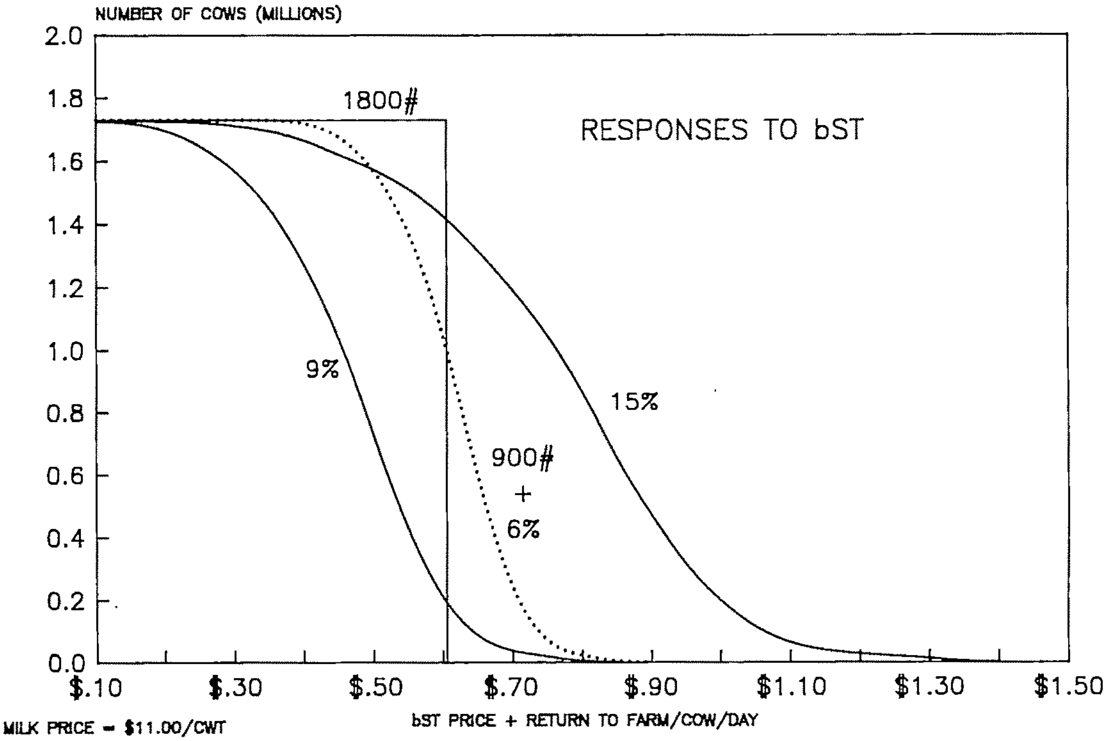

Figure 1. Estimated number of Wisconsin cows in 1989 on which bST will be economically feasible with different responses to bST

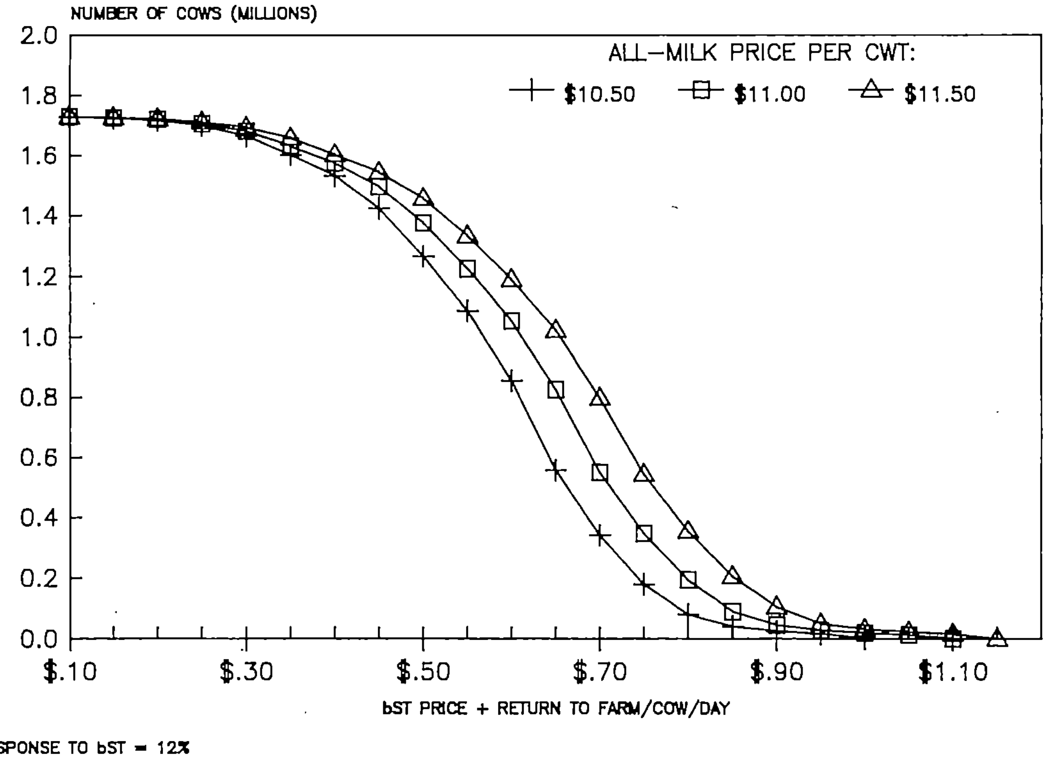

Figure 2. Estimated number of Wisconsin cows in 1989 on which bST will be economically feasible with different all-milk prices

low.[4] The first combination, normal feed prices and full variable costs, is used in all the other analyses in this paper.

Feed Prices	Other Variable Costs	Break-Even Production/ Cow	No. of Cows on Which bST Is Economical
a. Normal	.87/cwt	14,849	1,052,805
b. High	.87/cwt	15,973	850,109
c. Normal	.54/cwt	14,202	1,147,025

The results are relatively insensitive to changes in other variable costs (hauling, labor, veterinarian, breeding, and power). Using high rather than normal feed prices shifts the results in about the same magnitude as a 50¢ drop in milk prices.

Impact of bST on State Milk Production

Figure 3 indicates the percentage increase in state milk production that would occur in 1989 with different bST response rates if bST were given to all cows on which it is economically feasible and the all-milk price were $11.00. For bST price plus farm return of 50¢ to 70¢ per cow per day, the potential increase in state production ranges from roughly 1% to 14%, depending on the production response to bST.

Given the uncertainties about the response to bST, the price of bST and other factors, we developed lower and upper estimates of the percentage of cows on which bST will be economically feasible and the increase in state production that would occur if bST were given to all cows on which it is economically feasible (table 4). However, universal adoption by all farmers with feasible opportunities is unlikely. Enrollment experience with DHI suggests that bST might not be used on more than 45% of the state's cows, at least during the first few years of commercial use. That level of bST utilization would increase state milk production 4.9% to 6.5%, given the assumptions for table 4.

Impact of bST on Milk Prices

Increased milk supply due to bST is one of many factors that will influence future milk prices. We

[4] Other variable values are set as follows: bST response—12%; milk price—$11.00/cwt; bST price plus farm return—$.60/cow/day.

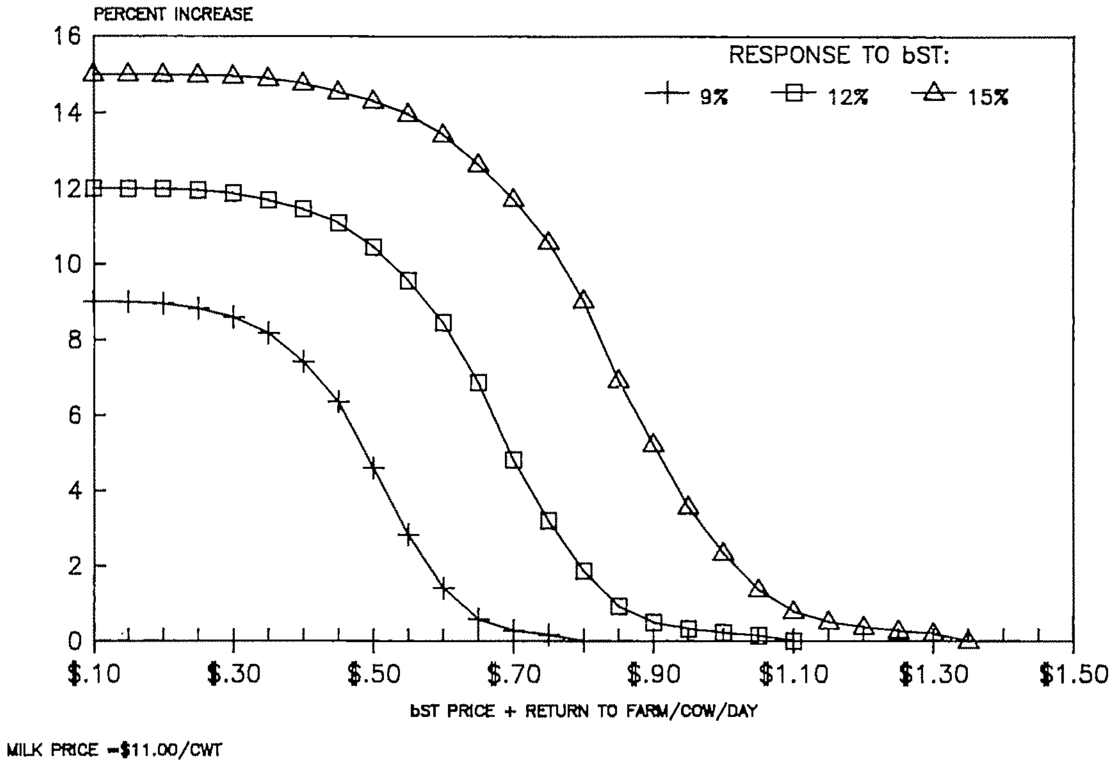

Figure 3. Percent increase in Wisconsin milk production with three different bST response rates, circa 1989

consider here only the incremental impact of bST on milk prices and assume that adoption rates of bST nationally will be similar to Wisconsin.

The estimated impact of bST on milk prices depends upon the federal dairy program in place during 1990–95. If the next farm bill continues the current program, federal support prices for manufactured grade milk can drop 50¢ per hundredweight in any year in which government purchases of dairy products are expected to exceed 5 billion pounds. Under this scenario, it seems reasonable to project a 50¢ per hundredweight decline in milk prices for every 5 billion pound increase in U.S. milk production attributable to bST. If U.S. milk production in 1990 without bST is about 155 billion pounds an-

Table 4. Upper and Lower Estimates of Percent of Wisconsin Cows on Which bST Will Be Economically Feasible in 1990

	Lower Estimate[a]		Upper Estimate[b]	
bST Price Plus Farm Return per Cow per Day	% of Cows on Which bST Is Feasible	% Increase in State Milk Production	% of Cows on Which bST Is Feasible	% Increase in State Milk Production
.40	56	5.9	92	11.5
.45	32	3.7	88	11.2
.50	15	1.8	83	10.8
.55	5	0.7	75	10.0
.60	2	0.3	66	9.1
.65	1	0.2	55	7.8
.70			41	6.0
.75			28	4.3

[a] bST response rate of 9%, all-milk price of $10.50/cwt., higher feed costs and full variable costs.
[b] bST response rate of 12%, all-milk price of $11.00/cwt., normal feed costs and lower variable costs.

nually, a 3.3% increase due to bST would lead to a 5 billion pound expansion in supply. In Wisconsin, the use of bST on the top one-fourth of the state's cows will increase state production about 3.3%. We believe it will take two or three years to achieve that level of adoption. If a similar scenario occurs nationally, milk prices would drop 50¢ per hundredweight at that point. An additional 50¢ decline could eventually be triggered.

The above analysis assumes that the present dairy program continues. An alternative dairy policy could allow prices to respond fully to market forces. With farm-level price elasticity of demand for milk of roughly −0.3, a 3% expansion in supply would lead to a 10% decline in milk prices, or roughly $1.10 per hundredweight. Thus, a free market for milk would result in bST having about double the price depressing effects as the current dairy program.

By comparison, Fallert et al. estimated a support price under the current dairy program of $9.60 per hundredweight in 1990 before bST is introduced (equivalent to Wisconsin all-milk price of about $10.25). Without bST, no further reductions in price supports would be required according to USDA simulation models. With bST, the USDA results indicated price supports would drop to $9.10 per hundredweight in 1991 and to $8.60 per hundredweight in 1992. This is a much sharper reduction in milk prices than we project, in part because Fallert et al. assumed a rapid rate of adoption and also because they assumed bST will be economically feasible for most dairy herds.

Effect of bST on the Structure of Wisconsin Dairy Farms

One of the issues surrounding bST is its likely effect on the economic viability of different size farms. Research to date indicates that adopting bST will not require large herds. However, effective use of bST will require careful management and may be more economically feasible on high-producing cows. Data on production per cow in Wisconsin indicate that herds with forty or fewer cows generally have lower production per cow than larger herds. A positive relationship between herd size and production per cow occurs with herds up to forty-five to fifty cows (table 5). For all herd sizes, substantial variation exists in the average production per cow.

Table 5 shows the proportion of Wisconsin herds in each size class in 1989 that had average herd production greater than several production levels. Regardless of the production level at which bST is economically feasible, herds with forty or fewer cows are less likely to find it economically attractive. The introduction of bST will place added financial pressure on farms with low producing herds for two reasons: First, such operators are less likely to find bST use profitable.[5] Second, adoption of bST by farmers with high producing herds is likely to lead to lower milk prices. On average, herds with fifty or more

[5] Of course, the financial pressures are a matter of degree. Farms that are far below the break-even production level will be at a greater disadvantage than those close to the break-even level. At the break-even level, farmers are indifferent between the returns they receive without bST and the returns, including compensation for administering bST, that they receive if they use it.

Table 5. Percent of Herds with Average Production Exceeding Various Production Levels by Herd Size, 1989 WASS Sample

Herd Size (No. of Cows)	No. of Sample Herds	Herd Average Production Per Cow/Year	Percent Exceeding Various Production Levels		
			12,000	16,000	20,000
1–10	19	11,022	31.6	15.8	5.3
11–20	81	11,901	44.4	18.5	6.2
21–30	158	12,599	56.3	22.2	3.8
31–40	235	13,899	68.5	30.6	6.4
41–50	202	15,272	81.2	46.5	9.4
51–60	152	15,934	87.5	50.0	13.8
61–70	84	15,787	84.5	51.2	9.5
71–80	69	16,387	89.9	55.1	11.6
81–90	29	16,437	89.7	58.6	10.3
91–100	30	16,429	86.7	63.3	16.7
101–150	74	15,936	89.2	50.0	8.1
>150	30	17,128	93.3	76.7	16.7
Total or Mean	1,163	14,666	74.6	40.6	8.8

Source: Wisconsin Agricultural Statistics Service

cows do not appear to be at a disadvantage relative to larger herds. BST will provide an added incentive for farmers to increase the productivity of their cows and improve their management practices in order to take advantage of the new technology.

Conclusions

Most of the previous prospective assessments of bST have concluded that bST will be profitable for most U.S. dairy farmers. However, these studies have assumed values for several key variables that may not exist when bST is introduced. Our analysis indicates that the economic feasibility and likely adoption of bST will be very sensitive to (*a*) the production response to bST, (*b*) milk prices, (*c*) the price that farmers will have to pay for bST, and (*d*) the returns required by farmers to adopt bST.

Based upon our analyses, we expect a more gradual and less extensive adoption of bST and a more modest impact on milk production and milk prices than most earlier studies. The economic impact of bST will still be significant, however. Our estimates indicate that if bST is used by one-fourth of U.S. cows (assuming a similar distribution of production/cow as in Wisconsin), milk supplies will increase enough to trigger a milk price decline of 50¢ per hundredweight (assuming continuation of the current dairy program). The three-fourths of Wisconsin herds that have not yet adopted bST will suffer a decline in net income of roughly $100 million per year. The one-fourth of the state's herds that are early adopters of bST will increase their net incomes during the period before milk prices decline. After the price drop, these farmers will find their net incomes are about the same as before bST was introduced. The projected effects echo Cochrane's comment that "technological advance puts farms on a treadmill" (Cochrane, p. 66). Other businesses and consumers will benefit to some extent (see Marion, Wills, and Butler for a fuller discussion).

Although our analysis is considered to employ more realistic assumptions than most previous studies of bST, the more important point is that the results of such studies, including this one, are very sensitive to the underlying assumptions. Given the speculative nature of all prospective assessments, greater emphasis on sensitivity analysis is warranted.

The Decision to Double Crop: An Application of Expected Utility Theory Using Stein's Theorem

Michele C. Marra and Gerald A. Carlson

A nonlinear, single-equation acreage allocation model derived from expected utility theory using Stein's theorem for covariance decomposition is developed. This decomposition allows the covariance of utility parameters and revenues to be expressed in terms of measurable variables. The model is applied to state-level data to estimate the relative importance of various economic factors in determining the pattern of double cropping wheat and soybeans in the southeastern United States. The hypothesis that the riskiness of returns is important in the aggregate is rejected for some of the states, although the constrained expected utility model without the effect of risk performs better than a standard wheat acreage response model.

Key words: double cropping, risk, risk attitudes, Stein's Theorem.

Small grain (primarily soft red winter wheat) production followed by soybeans is a multi-cropping system becoming widely used in the Southeast (Gallaher). This system, usually referred to as double cropping, has increased generally in the past fifteen years, and as much as 40% of planted soybeans are in this system in some years. However, it has neither advanced steadily like many agricultural innovations nor proceeded at the same rate in all states in the Southeast. From 1976 to 1979 and again in the mid-1980s double-cropped soybeans as a proportion of total soybean acreage decreased in general in the Southeast (Marra and Carlson).

Double-cropped soybeans are usually planted thirty to fifty days later than full-season soybeans and harvested at the same time. They generally are expected to have lower average yield and more yield variability than full-season soybeans.[1] They may require more management input and pesticides, but extra income from a wheat crop may offset the lower and riskier total revenue from the late-planted soybean crop.[2] Also, the income-stabilizing possibilities of growing two commodities with offsetting price movements and reduced technical risk from a mixed temporal and spatial exposure to drought and pest threats are attractive. Some farmers have contended that receiving income from wheat in the middle of the typical production year makes double cropping more desirable (Jordan and Harris).

This paper has two objectives. The first is to propose a model of individual decision makers who must allocate a fixed resource between two outputs which have uncertain and possibly interdependent returns. This acreage allocation decision model can be estimated without a priori knowledge of the risk attitudes of the decision maker. The second objective is to use the decision model to explain the aggregate pattern of double-cropped wheat and soybeans in the southeastern United States with emphasis on predicting future use patterns and assessing the relative importance of factors affecting double-cropped acreage.

Understanding the future course of double

Michele C. Marra is an assistant professor, University of Maine, and Gerald A. Carlson is a professor, North Carolina State University.

Maine Agricultural Experiment Station Publication No. 1402. This work was accomplished in part through the support of Cooperative Research Agreement No. 58-319V-4-00232, RTD/ERS/USDA.

The authors wish to thank Dwight Grant, Bob Collender, Jim Chalfant, Steve Hatchett, Ron Gallant, and the *Journal* referees for many thoughtful comments on earlier drafts. Responsibility for remaining errors rests with the authors.

[1] For example, Debrah and Hall found for a sample of 49 Kentucky farms that the coefficient of variation on soybean yield was 54% higher but average yield was 39% lower for double-cropped compared to single-cropped soybeans.

[2] McArthur showed that pesticide expenditures were higher on double-cropped soybeans; Marra and Carlson conclude that input expenditures differences are declining in recent years. Minimum tillage, a component of more double-cropped systems, requires higher levels of management (Rahm and Huffman, Lewis and Phillips).

cropping with its changes in pesticide use, tillage practices and management requirements could be useful for research allocations and policies on soil conservation and pesticide use (Kramer, McSweeny, and Stavros). In addition, both wheat and soybean carryover stocks are linked to double cropping. Estimates from this model allow one to recover acreage response elasticities for the major factors affecting double-cropped acreage.

Standard approaches for evaluating technology adoption include fitting logistic functions to aggregate data (Griliches) or estimating dichotomous choice models (Rahm and Huffman, Burrows). These models are limited by their exclusion of yield and price variances and covariances and by their inflexible forms. Acreage adjustment models which have included uncertainty typically have been limited to single commodities without consideration of enterprise covariances (e.g., Behrman), though Just suggests how covariance might be included in a partial adjustment framework. Multiple-enterprise innovations have unique price and cost structures. Input use and yield per acre can differ between a given crop grown in two distinct ways even though the product price is the same. The riskiness of such innovations involves the covariances in output prices as well as yields. Relatively new methods are available to decompose covariance terms so that one need not ignore them or resort to restrictive assumptions on utility functions (Grant).

The Theoretical Model

In this section a decision model is developed which allows explicitly for the effect of the covariance of returns but which is a function of observable variables. The individual producer faces a decision involving two possible enterprises or outputs: full-season soybeans and double-cropped wheat and soybeans. His objective is to maximize the expected utility of profit from his chosen soybean acreage, L, by the optimal choice of the proportion, Y, of the acreage to be double-cropped.[3] The utility function, U, is defined on one-period profit, π, where uncertainty can arise from variable price and yield. The standard utility assumptions apply, except that, through the use of a covariance decomposition method known as Stein's theorem (Grant, Rubenstein) the sign and magnitude of the first and second derivatives of the utility function (and, hence, Pratt-Arrow risk attitudes) need not be specified or imposed in advance. These parameters of the utility function become estimated parameters in the model, allowing the data to reveal risk attitudes rather than having to resort to imposing ad hoc or exogenously determined measures on the model.

The individual's utility of profit is defined as

$$(1)\quad U(\pi) = U[(\alpha P_s SY + rP_w WY + P_s S(1 - Y) - C(Y, r))L],$$

where $U(\pi)$ is utility of profit from the soybean acreage; α, the ratio of double-cropped soybean yield relative to full-season soybean yield, $0 < \alpha \leq 1$; P_s, the uncertain market price of soybeans per bushel; S, the uncertain yield of full-season soybeans in bushels per acre; Y, the share of total soybean acreage double-cropped; r, 1 + the opportunity interest rate on operating capital; P_w, the uncertain market price of wheat per bushel; W, the uncertain yield of wheat in bushels per acre; $C(Y, r)$, the total cost of production per acre for the soybean acreage including both the single- and double-cropped acreage; and L is the total acreage planned to be either single or double cropped.

Equation (1) is a function of four random variables, P_s, S, P_w, and W. The specific form of Stein's Theorem used here requires the assumption that total revenues are bivariate, normally distributed random variables even though no specific assumption about the distribution of yield is implied. The producer maximizes the expected utility of profit, $EU(\pi)$, with respect to the proportion of total soybean acreage double cropped, Y. This is a utility function with one control variable similar to one which Pope examines using a primal-dual approach. The first-order condition for a maximum, FOC, can be written (with $'$ denoting derivatives) as

$$(2)\quad FOC = \delta EU(\pi)/\delta Y = E\{U'(\pi)[(\alpha P_s S + rP_w W - P_s S - C'(Y, r))L]\} = 0.$$

The change in the expected utility of profit from a one-unit change in the double-cropped proportion, Y, is the expected marginal utility of additional revenue from the double-cropped acreage minus the foregone revenue from the single-cropped acreage less the net addition to total cost from the increase in double-cropped area. C' is the marginal cost of shifting area from single to double-cropped soybeans, rather than

[3] The multiproduct diversification possibilities have many similarities to a technology adoption model by Just and Zilberman.

the traditional marginal cost as a function of output.

Taking the expectations operator, E, through (2) gives

$$(3)\quad EU'(\pi)\{[(\alpha-1)E(P_sS)+rE(P_wW) - C'(Y,r)]L\}+(\alpha-1)L \operatorname{cov}(U'(\pi),P_sS)+rL\operatorname{cov}(U'(\pi),P_wW)=0.$$

Dividing through by L and applying Stein's Theorem to $\operatorname{cov}(U'(\pi), P_sS)$ and $\operatorname{cov}(U'(\pi), P_wW)$ gives

$$(4)\quad EU'(\pi)(\alpha-1)E(P_sS)+EU'(\pi)rE(P_wW) - EU'(\pi)[C'(Y,r)]+(\alpha-1)EU''(\pi) \cdot\{(\alpha Y-Y+1)L\operatorname{var}(P_sS) + rYL\operatorname{cov}(P_sS,P_wW)\} + rEU''(\pi)\{(\alpha Y-Y+1)L\operatorname{cov}(P_sS,P_wW) + rYL\operatorname{var}(P_wW)\}=0.$$

Stein's theorem allows one to find an exact representation of the unobservable covariance of marginal utility and crop revenue in terms of observable variances and covariances of wheat and soybean revenues.[4] The Stein result is that for random variables C and D, the covariance of C and $g(D)$ is $Eg'(D)\operatorname{cov}(C, D)$ (Rubenstein). The covariance decompositions in (4) use this result and various substitutions for π and the variances of returns. An example of the algebraic steps of the decomposition is available from the authors upon request.

The Empirical Model

The relatively short time series available for this application allows only a few parameters to be estimated and, therefore, certain simplifications were necessary. Multiyear considerations, such as crop rotations to combat pests or conserve nitrogen and soil, are important on individual farms, but they will be ignored in this state-level study. Also, to comply with the only available primary data on double cropping, the share of total soybean acres double cropped (not total double-cropped acres) is the dependent variable. Total soybean acreage is affected by a broad range of factors, but these are assumed independent from the double-cropping decision. We recognize that this is a strong separability assumption for multiproduct firms; the multiproduct methods of Antle and Aitah and the approximate separability tests of Shumway may be helpful in assessing the seriousness of bias introduced by this assumption. The available double-cropping data only allow a lower mean return for the double-cropped soybeans to be included in the model. Although the yield variance of double-cropped soybeans is expected to be different, as well, no double-cropped yield data were available to make this distinction. The lower mean revenue from the double-cropped soybeans is a result of lower expected yields. Because both soybean types are harvested at the same time, output price will be the same for each. The model does imply diversification possibilities through the statistical dependence between the revenues of the three crops: wheat, full-season soybeans, and double-cropped soybeans.

Because this is a model of individual behavior applied to aggregate data, output level will surely affect output price. This effect was circumvented by treating output price as an endogenous variable by using the appropriate futures price as the expected price. Also, from Holthausen it is clear that opportunities to participate in futures markets may affect production decisions; price expectations were quantified by the use of quotations from futures contracts for soybeans and wheat following Gardner, but we ignore explicit inclusion of hedging opportunities in this application in the interest of tractability and data availability.

No explicit fixed cost of adoption is considered. The focus is on the land allocation decision. This adoption decision is unique in that it is made every year in which soybean acreage is planned. Once the first decision to double crop is made, the fixed adoption costs become sunk relative to future adoption decisions. In the empirical analysis, however, any amortized costs of additional equipment required for double cropping are captured in the measure of marginal adjustment cost of acreage, $C'(Y, r)$.

The opportunity interest rate is included implicitly as a component of total cost, $C(Y, r)$, and the revenue from the wheat crop, rP_wW. In a double-cropped system the producer must borrow operating capital earlier in the growing season to plant the wheat crop, but he also has the opportunity to use the mid-period wheat income to defray some operating costs later in the season.

Only the marginal cost of shifting area from single to double cropping needs to be measured to make the cost component of the model operational. Separate total cost functions for each of the three crops are not needed in the speci-

[4] Dwight Grant introduced us to this theorem, and we record here our indebtedness. For examples of formal proofs, see Amemiya or Rubenstein.

fication of (4). The marginal cost term is denoted as GY and it replaces $C'(Y, r)$ in (4), leaving the interest rate effect implicit in G. The term G is the marginal adjustment cost per acre. This adjustment cost is measured using state-level budget data on full season soybeans and double-cropped wheat and soybeans as described below in the data section.

Solving (4) for optimal Y (denoted as Y^*), rearranging terms, and using the relation for the expectation of the product of two random variables: $E(CD) = E(C)E(D) + \text{cov}(C, D)$, gives[5]

$$(5)\quad Y^* = [EU'(\pi)X_1 + EU''(\pi)X_2]/[EU'(\pi)X_3 + EU''(\pi)X_4],$$

where Y^* is the optimal proportion of soybean acreage double cropped, X_1 is $(1 - \alpha)EP_sS - rEP_wW$, X_2 is $(1 - \alpha)L\ \text{var}(P_sS) - Lr\ \text{cov}(P_sS, P_wW)$, X_3 is $-G$, and X_4 is $(\alpha - 1)^2L\ \text{var}(P_sS) + r^2L\ \text{var}(P_wW) + [2(\alpha - 1)]rL\ \text{cov}(P_sS, P_wW)$.

We arrive at the equation to be estimated by normalizing on $EU'(\pi)$. If constant absolute risk aversion is assumed, then the normalized ratios, $EU'(\pi)/EU'(\pi)$ and $EU''(\pi)/EU'(\pi)$, can be thought of as constants that do not depend on the elements of π. The estimating equation is

$$(6)\quad Y^* = (B_1X_1 + B_2X_2)/(B_3X_3 + B_4X_4) + \in,$$

where $B1$ and $B3 = EU'(\pi)/EU'(\pi)$ and $B2$ and $B4 = EU''(\pi)/EU'(\pi)$. The error term ($\in$) is assumed to have an expected value of zero, is uncorrelated with the X's, and takes into account additional factors known to decision makers but not observable by the authors. This parameterization of the first-order condition for expected utility maximization is similar to that used by Antle and derived in an alternate manner by Just and Zilberman.

The Data

The study area is the set of eight southeastern states in the United States for the 1968–86 period. This region has undertaken the most double cropping and has the most complete data available (Louisiana and Mississippi are omitted because of incomplete data). Data requirements for each state and year include total soybean planted acreage, expected total returns from each crop, the variances and covariance of the revenue for each enterprise, the relative yield of single- and double-cropped soybeans, the cost of operating capital, and production costs for both cropping systems for the period of the analysis. Expected total revenue, variances, and covariances of the revenues were calculated using state-level yield data from the three crop years prior to the decision year. Following Gardner, the November quotation for the appropriate futures contract is used as the expected price for each crop. The state average yields and season average crop prices are taken from USDA's *Agricultural Statistics*. Futures prices are taken from the Chicago Board of Trade's *Statistical Annual*. All prices are deflated by the index of prices paid by farmers (1977 = 100) (USDA). The standard variance and covariance formulas were applied to data from the three previous crop years, producing a time series for each of these variables. This method of calculation adheres to the guidelines suggested by Young and used by Behrman for representations of risk in time-series analysis. Modeling a rational expectation formation process for crop revenue might be preferred, but with a limited time series we chose a simple three-year, moving-average process for expected yield and assumed that farmers use futures price information in their expectation formation. The use of state-level yield and price information in the variance calculations may introduce some aggregation bias because the variance faced by individual farmers may be larger than the variance calculated at the state level.[6] County-level yield data from North Carolina were used to estimate the parameters of the model. Little difference in the county estimates relative to those using state-level data was found (Marra and Carlson). Statistically significant parameter estimates associated with the variances and covariances are more likely to be found with individual farm data.

The yield of double-cropped soybeans relative to full-season soybeans, α, is available from the 1978 and 1982 USDA cost of production surveys. A logistic time trend for α for each state

[5] Just and Zilberman analyze a similar problem of land allocation to two technologies, one traditional and one modern. They assume a significant fixed cost of adoption of the new technology and, thus, their method leads to two decisions: the adoption decision and the land allocation decision, given the adoption decision. To derive their result, the standard mean-variance utility function assumption was applied. With our theoretical derivation, we have not relied on a mean-variance utility function or a Taylor series approximation. It is possible to estimate a measure similar to a Pratt-Arrow risk aversion coefficient based on real-world decisions by applying our model to appropriate farm-level data. Taking $EU'(\pi)$ and $EU''(\pi)$ as first order approximations of $U'(\pi)$ and $U''(\pi)$, the approximate mean Pratt-Arrow measure of risk attitudes can be estimated with appropriate microlevel data (Antle).

[6] Debrah and Hall found that coefficients of variation in net income were about twice as high for individual farms as for county aggregates for all soybeans.

was calculated using these two years as reference points. Not all states' relative yields were reported in both surveys, so experimental information was used in some cases to fill in missing data. For farmers in those states reported in both surveys, α increased from 1978 to 1982, reflecting the improvement in pesticides available, soybean and wheat varieties suitable for double cropping and, probably, producers' increased management abilities as they learned more about the new cropping system (Marra and Carlson).

Data on actual production costs for the two cropping systems are sparse. A time-series, cross-section regression model was fit to twenty-three observations from state budgets to fill in missing data points over the 1968 to 1986 period. The difference in per acre production costs between double-cropped wheat-soybeans and full season soybeans was regressed on a cubic regression of time and state dummy variables ($R^2 = .8$). These estimated costs, deflated by the method described above, became the data for G in the state-level estimation of the parameters of (6).

The cost of operating capital is the average Production Credit Association interest rate for the year just preceding the crop year (USDA), which corresponds to the expected time of the acreage allocation decision. All costs and returns are appropriately compounded for comparison at harvest.

Total soybean planted acreage and the proportion of soybean acreage double cropped were taken from unpublished USDA survey data and USDA *Crop Production* bulletins. For each state, the 1972 and 1973 proportions were missing. A proxy was based on the correlation between the proportion of total soybean acreage planted in narrow rows and the proportion double cropped. The proxy was tried for these two years for Arkansas and a slight improvement in the residual sum of squares was obtained. Data were unavailable to try this procedure for the other states, however, so these two years were omitted from the final estimations.

Estimation Methods, Tests for Model Selection, and Results

This section contains the empirical results. First, the results of estimating the parameters of the full expected utility model [equation (6)] are presented for the individual states in the study. Then, the results of estimating the parameters of a model that retains the structure of the full expected utility model, but where the parameters associated with variances and covariances of returns are constrained to equal zero (the constrained expected utility model) are discussed. Next, the regression results of a standard wheat supply model are presented for comparison. Various statistical comparisons of the three models are then presented and discussed. A discussion of elasticities from the model that was judged to be the best of the three is presented last. All of the empirical results presented here are based on estimation of a separate model for each state in the study. We also tried a pooled time-series cross-section model in an attempt to improve the efficiency of the parameter estimates. We found, however, that the pattern over time of double cropping in the individual states studied is sufficiently different that a regional model did not result in improved estimates.

The parameters of equation (6), which is nonlinear in the parameters, were estimated for eight southeastern states using data from 1968 to 1984 (except for 1972 and 1973). The modified Gauss-Newton algorithm (SYSNLIN, SAS) for single-equation, nonlinear regression was employed to obtain the parameter estimates given in table 1. All of the signs on $B1$ and $B3$ in the full expected utility model are as expected. Recall that $X_1 = (1 - \alpha)EP_sS - rEP_wW$, which is the negative of the additional net returns from one additional double-cropped acre. Therefore, $B1$ is expected to be negative. Also, since $X_3 = -G$, which is the negative of the marginal acreage adjustment cost and appears in the denominator of the estimating equation, $B3$ also is expected to be negative. Eight out of sixteen parameter estimates (at least one in six out of the eight states) associated with the variances and covariance of returns ($B2$ and $B4$) are statistically significant when tested using t-tests of the individual parameters (table 1). The signs on $B2$ and $B4$ depend on the signs and relative magnitudes of the variance and covariance terms involved. Therefore, there is no theoretical basis for assigning expected signs to these two parameters.

All parameter estimates in tables 1 and 2 are relative to the value for $B3$, which was fixed by the estimation routine. This underidentification problem is expected for this equation because the parameters to be estimated are representations of (or, at least, contain) utility function parameters, which are unique only up to a positive linear transformation. A normalization rule, such as setting $B3 = 1$, for all states was judged to be too restrictive, given the differences in state-

level costs and the results of attempts to estimate the parameters of a pooled, regional model.

In addition to the full expected utility model given in (6), the parameters for two other specifications were estimated. First, the constrained expected utility model with the assumption that risk does not matter or that the individual responses to risk are masked in the aggregate was estimated (table 2). The results from the linear wheat acreage response model with input and expected output prices are presented in table 3. The parameters of the constrained expected utility model were all statistically significant and all had the expected signs. The wheat acreage response model generally performed well in terms of the signs of the parameter estimates, although most were not statistically significant. Although not reported to save space, the price elasticities from the acreage response model imply quite elastic responses in most cases.

Note: Nonlinear regression estimates of equation (6) with parameters $B2$ and $B4$ set equal to zero; sample size is 12 for each regression.
[a] Parameter estimate is statistically significant using the decision criterion, $t^* > t(10, .025) = 2.2$.

As a first comparison of the full model and the constrained model, likelihood ratio tests were performed to test the hypothesis that the parameters involving expressions of the variance and covariance of crop returns were equal to zero in the full model ($B2 = B4 = 0$). This hypothesis was rejected for four out of the eight states ($H1$ in table 4). This provides some evidence to suggest that risk may matter in the aggregate, but it is not conclusive.

The theoretical derivation implies that, for an individual decision maker, $B1$ should equal $B3$ and $B2$ should equal $B4$. Because of aggregation to the state level, however, the parameter estimates in the expected utility models are not expected to represent exactly the first-order approximations of the first and second derivatives of U as would be the case if they were estimated from data at the microlevel. This is supported by the results of likelihood ratio tests of the hy-

pothesis that $B1 = B3$ and $B2 = B4$ in the aggregate state level regressions ($H2$ in table 4). The aggregation function, in fact, can be quite complicated, and this model applied at the state level is an obvious abstraction of the true aggregated model. Any nonlinear micromodel applied at an aggregate level would have the same problem. Models derived from consumer utility maximization leading to demand estimation at the aggregate level are common examples of this (e.g., Huang). The trade-off is between the bias implied by assuming a relationship is linear when it is not and the bias implied by assuming the correct functional form at the microlevel and imposing bias through aggregation.

To investigate further the relative performance of the three models, we calculated the mean square prediction error from out-of-sample predictions in 1985 and 1986 for each of the models. The results are reported in table 5. On this basis of comparison the constrained expected utility model performed better than either competing model in all states but South Carolina, where the wheat acreage response model was the best. In four out of eight states the full expected utility model performed better than the wheat acreage response model.

Elasticities from the constrained expected utility model are presented in table 6. They are calculated by taking the partial derivative of Y^* [equation (5)] with $B2$ and $B4$ equal to zero and putting the partial effect in percentage terms. The partial derivatives in this case are functions of the parameter estimates and the exogenous vari-

ables. All of the elasticities have the expected signs. The elasticity with respect to expected wheat revenue generally is four to five times larger in absolute magnitude than the elasticity with respect to expected soybean revenue. This is reasonable because, as expected soybean revenue increases, full-season soybeans become more valuable, but so do double-cropped soybeans. On balance the effect should favor full-season soybeans but to a smaller extent than would a similar change in expected wheat revenue. The elasticity with respect to changes in the cost of increasing double-cropped acreage is similar on average (in absolute value) to the effect of changes in expected wheat return. At first glance, the elasticities appear small in absolute magnitude. However, soybean acreage in the Southeast amounts to 12 to 14 million acres in most years, so a slight change in the proportion double-cropped can mean a significant change in wheat acreage.

Virginia	−0.00025	0.00126	−0.00099

Note: Computed from parameter values in table 2 using the definitions of equation (5).

Conclusions and Limitations

Because the time series used for estimation is relatively short and nonlinear hypothesis tests are only asymptotically valid, none of the statistical tests reported above are exact. The conclusions, therefore, must be based on a preponderance of the evidence presented.

There is some evidence (t-tests in table 1, F-tests of $H1$ in table 4, and relative, out-of-sample predictive ability in table 5) to suggest that the full expected utility model has value in aggregate estimation. The evidence is more convincing, though, that a model derived from the expected utility hypothesis (the constrained expected utility model) can contribute more to the understanding of acreage allocation decisions of this type than an acreage response model similar to those generally found in the literature (table 5).

The decision model developed here remains to be tested with data at the microlevel. The aggregate results suggest that the expected utility model has some merit when compared to the standard acreage supply models in understanding acreage allocation between two cropping systems.

The main limitations of the proposed method are that greater demands are placed on assembling price and quantity data, and that a nonlinear estimation procedure is required. The model has been estimated without exploiting possible primal-dual restrictions on the utility function, which Pope has suggested for similar objective functions. Future developments may show that Stein's covariance decomposition theorem also extends to other, nonsymmetrical probability distributions. Generalization of the model to more than two commodities with more complete cost specification seems possible; this probably would help to explain adoption of various technologies. Also, more applications of the model are needed with alternate revenue expectation formation processes. Finally, this decision model should be applied to a farm-level data set to

evaluate its usefulness for estimating risk attitudes from observed production decisions. We agree with Antle when he calls for a comparison of the usefulness of all of the proposed methods for evaluating risk attitudes and their effects on production decisions.

Orderly Marketing for Lemons: Who Benefits?

Hoy F. Carman and Daniel H. Pick

The orderly marketing goal of federal marketing orders may deal with price stability or uniform flow of product to market, a choice which can have important economic implications. This study examines the impact of four fresh lemon marketing strategies on returns at the producer, FOB, and retail levels, together with marketing margins and consumer surplus. Producers, as a group, and consumers should favor a constant price strategy. Some individual producers and middlemen, however, enjoyed higher returns with constant weekly sales. Explanations of the shift in lemon sales patterns which occurred during the 1970s is examined in light of these results.

Key words: lemon marketing, marketing orders, orderly marketing.

The California–Arizona lemon industry can, on a weekly basis, recommend to the secretary of agriculture that the quantity of lemons shipped to the domestic fresh market be limited under provisions of its federal marketing order program. Designed to benefit lemon producers by increasing average prices to a level of parity prices, the weekly prorate feature of the lemon marketing order is justified as contributing to "orderly marketing." The concept of orderly marketing, while central to marketing policy embodied in the Agriculture Marketing Agreement Act of 1937 (AMAA), as amended, is not defined in the basic statutory framework for agriculture marketing orders. The declaration of policy in the AMAA, however, does associate orderly marketing with an even flow of product to market at stable prices. This is consistent with a General Accounting Office (U.S. Comptroller General) statement that "an orderly market would (1) reduce fluctuations in farm and retail prices, and (2) assure consumers a steady supply of quality products that meet consumer needs" (p. 2).

There is a seasonal pattern of demand for fresh lemons with demand being highest during the summer months of June and July and lowest during the winter months. Because of seasonal demand, stable weekly sales tend to lead to variable prices and variable weekly sales can lead to stable prices. An examination of the weekly pattern of lemon sales and prices over the 1961 through 1987 period reveals a dramatic change in marketing policy followed by the Lemon Administrative Committee (LAC) for the periods before and after 1973. Weekly lemon shipments were quite variable and prices were relatively stable from 1961 through 1972, while shipments became much more stable and prices much more variable 1974–87. While the changing pattern of shipments and prices appears rather discrete, annual LAC reports do not mention any change in marketing policy. Either weekly sales pattern can be justified as contributing to orderly marketing, but the economic results from a policy that attempts to stabilize sales can be quite different from a policy that attempts to stabilize prices.

The purpose of this article is to examine possible reasons for a change in fresh lemon shipment patterns from one which demonstrated considerable seasonal variability to one which became much more stable. We assume that shipment pattern changes benefitted one or more groups that influenced Lemon Administrative Committee decisions. While one would expect that lemon producers were the primary beneficiaries, it is not clear that they were. Returns to

Giannini Foundation Research Paper No. 917. Support of the Lemon Administrative Committee is gratefully acknowledged.

The authors appreciate the helpful comments of Colin Carter, Julian Alston, and two anonymous *Journal* reviewers on earlier drafts of the manuscript.

producers, marketing margins, retail level expenditures, and consumer surplus for alternative weekly shipment patterns will be estimated. Possible gainers and losers from a changing pattern of fresh lemon sales, based on total 1986–87 shipments, will be examined. This information will be used to evaluate four hypotheses for the changes observed. They are:

Hypothesis I: The LAC was responding to pressures from administrative agencies to increase fresh market shipments. Recall that supply control provisions of marketing orders were targeted as contributing to price inflation in the early 1970s.

Hypothesis II: The LAC was attempting to improve producer returns.

Hypothesis III: The LAC was responding to pressure from marketing middlemen.

Hypothesis IV: The significant growth of the export market for lemons, beginning in 1971–72, led to a changed seasonal marketing pattern.

Lemon Marketing

The California–Arizona lemon industry has had a federal marketing order program since 1941. Under this program, the Lemon Administration Committee recommends a weekly allotment of lemons for shipment to the domestic fresh market, the recommendation is routinely approved by the secretary of agriculture, and this allotment is then "prorated" among handlers based on the quantity of lemons picked by their growers during a specified period of weeks. The weekly prorate feature of the marketing order was used each marketing year from 1961–62 through 1987–88, except for 1985–86. Establishing maximum weekly fresh market shipments provides a means of price discrimination for the lemon industry because any lemons in excess of the prorate quantity can only be processed or exported. Quantitative analysis indicates that price elasticity of demand is more inelastic for fresh market sales than for fresh exports or processing sales (Kinney et al.), and annual data on allocation by markets combined with average price data indicate that weekly prorate has helped the lemon industry to maintain a significant price difference between fruit going to fresh and processing uses. Average annual on-tree prices for lemons utilized for processing were negative for twelve of the fifteen years from 1972–73 through 1986–87, while on-tree prices for lemons sold for fresh use ranged from a low of \$2.11 per carton in 1976–77 to a high of \$7.72 per carton in 1985–86 (USDA *Fruit Situation*.)[1] Crop utilization varies annually but during the five-year period 1982–83 through 1986–87, an average of 51% of the lemon crop was processed while 31% went to domestic fresh markets and 18% was exported for fresh use (Lemon Administrative Committee).

The California–Arizona lemon industry has seasonal patterns of production, harvest, and marketing. District 1 (Central California), with 14% of total acreage, usually begins harvest in October or early November, reaches a peak in January and February, and typically ends in April or May. District 2 (Southern California), which currently accounts for approximately 49% of lemon acreage, harvests and sells lemons throughout the year, but most of its fruit is picked from January through July. District 3 (California desert and Arizona), which has about 37% of total acreage, has a harvest period that begins in late July or early August, usually peaks in November and extends into February or March. Significant quantities of lemons are stored by all districts throughout the year, but especially by District 2 during the April through July period.

The relative importance of production districts has changed over time. In 1963, District 1 had only 3% of total lemon acreage, while District 2 had 85% and District 3 had 12%. Because of large new plantings, District 1's share of acreage increased to 12% and District 3's share increased to 36% in 1973, while District 2's share decreased to 52%. A review of annual reports of the Lemon Administrative Committee shows that the membership of the committee also changed in line with acreage and production. There were no grower or handler members from District 1 and 3 prior to 1 July 1971. The marketing order was amended and the secretary of agriculture appointed a new committee with members from Districts 1 and 3 to serve for the period 1 July 1971 through 31 July 1972. The term of office for committee members, appointed by the secretary of agriculture to represent various industry interests, is two years.

Shipment and Price Variability

An examination of the variability in lemon sales and prices by marketing year illustrates the changes taking place. As shown in figure 1, the

[1] Returns for lemons used for processing are positive at the packing house; but costs of handling, transportation, and picking sometimes exceed these returns, resulting in a negative on-tree price.

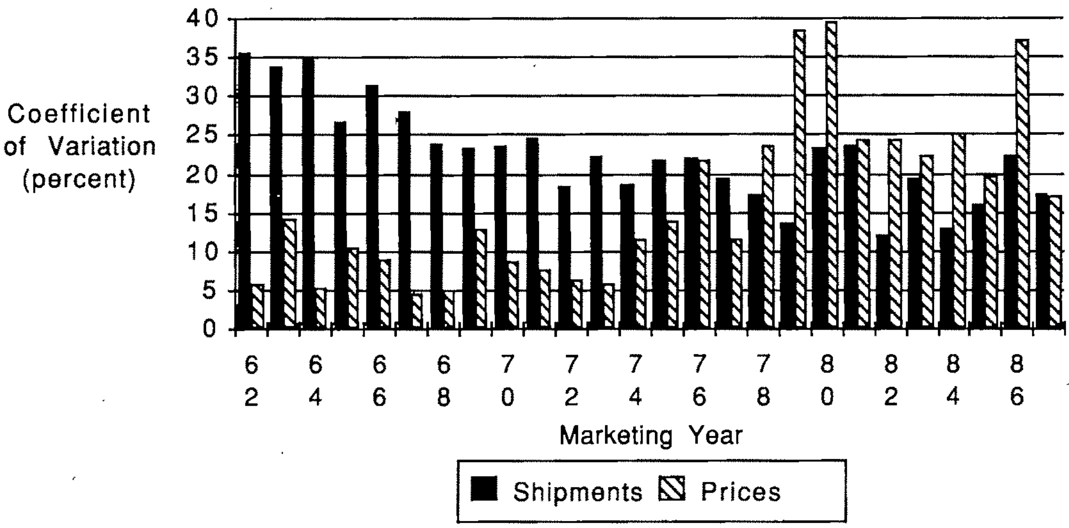

Figure 1. Coefficients of variation for annual shipments and prices of fresh market lemons, 1961–62 through 1986–87 marketing years

variability of annual lemon shipments (as measured by the coefficient of variation) decreased over time while the variability of annual prices increased. Increased variability of prices is particularly evident after the 1973–74 marketing year. An examination of the seasonal pattern of fresh lemon shipments indicates that the proportion of each year's crop sold in the second and third quarters of each marketing year (Nov.–April) tended to increase slightly over time while the proportion sold in the first and fourth quarters decreased.

An Analytical Framework for Lemon Pricing

Examination of the impact of alternative patterns of weekly sales on revenues requires estimation of the weekly demand for fresh lemons. Several empirical studies provided estimates of demand relationships for lemons (Hoos and Seltzer, Hoos and Kuznets, Nicolatus, Carman and Pick). This research builds on demand relationships in the Carman and Pick study of the impact of not using weekly prorate during the 1985–86 marketing season.

Carman and Pick estimated a linear inverse demand function for fresh lemons with weekly real FOB price specified as a function of weekly per capita fresh sales, real consumer income, lagged weekly prices, seasonal demand shifts, and a dummy variable to measure possible shifts in structure due to suspension of prorate. The use of a partial adjustment analytical framework was based on the observation that FOB prices are sticky and adjust to new equilibrium values over time rather than instantaneously. A portion of this stickiness may result from the stable nature of weekly shipments during the observation period. Processed substitutes were not included in the model, a weakness attributable to the lack of suitable data series for lemon juice and frozen lemon concentrate. There is a series on the quantity of lemons processed each year, but prices and quantities by product category and year-end inventory data required to calculate consumption are not recorded. A final limitation is that data needed for a grade variable were not available even though prices vary by grade. The proportion of fresh sales in each grade is reported, but FOB prices by grade and size are not.

This study expands on the demand relationship described above by extending the data series and by expanding the bimonthly seasonal demand shifters to weekly shifters. Several approaches are available for determining the nature of the seasonal demand shifter. These approaches include (*a*) treat all observations as a single data set and distinguish subperiods through the use of dummy variables, (*b*) distinguish subperiods (e.g., weeks or summer-winter) and treat data for each subperiod as a separate set of observations, (*c*) use a random coefficients model,

or (*d*) use a sine or cosine function.

Under perfectly competitive conditions, primary demand is at the retail level with demand at lower levels in the marketing system derived from retail demand. Thus, prices are established at the retail level by supply and consumer demand and prices at the wholesale; FOB and farm levels are derived by subtracting the relevant marketing margins. If equilibrium conditions are assumed, marketing margin relationships can be used to derive demand at one level in the system from demand at another level. Empirical studies of the food industry (Heien, Ward) provide strong evidence of markup-type pricing with prices registered at the wholesale or FOB level and then transmitted to the retail level by middlemen and store managers. The markup pricing model appears to fit the fresh lemon industry with major price changes first registered at the FOB packinghouse level in the distribution system. Working backward from the FOB level to the farm, a constant annual charge for packing, transportation, and picking is subtracted from the FOB price to arrive at a farm-level on-tree price.

Price and quantity data necessary to estimate weekly demand functions for fresh lemons are available only at the FOB level. Analysis of the impact of different marketing policies on retail expenditures, therefore, must be based on FOB prices and estimated marketing margin relationships. A common approach has been to assume that the marketing margin is constant, even though there is substantial evidence of variability in margins. Alternative margin specifications include a percentage margin, where the margin is a constant percentage of the retail or FOB price, and a combination margin consisting of both constant dollar amounts per unit of product (as for packing or transportation) and a percentage component.

Recent research for fruits and vegetables has found evidence of marketing margins which are asymmetric to price changes (Ward). Discussions with industry participants revealed a widespread perception that retail prices are sticky and that they typically respond more rapidly to FOB price increases than to price decreases. This type of pricing can be modeled with the price linkage equation:

$$(1) \quad PR_t = b_0 PFU_t + b_1 PFD_t + b_2 T + e_t,$$

where PR_t is the change in retail price (P_t) in period t from the base period (P_0), PFU_t is the sum of increases in the FOB price (PF_t) up to period t and PFD_t is the sum of decreases in the FOB price up to period t. For estimation, equation (1) is

$$PR_t = P_t - P_0$$

$$PFU_t = \sum_{t=1}^{n} \Delta PF_t, \quad \text{if } PF_t > PF_{t-1}, \quad \text{and zero otherwise}$$

$$PFD_t = \sum_{t=1}^{n} \Delta PF_t, \quad \text{if } PF_t < PF_{t-1}, \quad \text{and zero otherwise}$$

$$T = \text{a time trend variable;}$$

where $\Delta PF_t = (PF_t - PF_{t-1})$ is the change in FOB price from period $t - 1$ to period t.

If FOB and retail prices move up and down together, then b_0 and b_1 will be positive. If the retail price response to changes in FOB price is symmetric for both price increases and decreases, then one would expect to find $b_0 = b_1$. The relationship between FOB and retail prices can be expected to change if costs of performing the marketing functions change and these costs have been increasing over time. A trend variable (T) is included to detect any systematic changes in marketing costs over the period of analysis. The alternative of a weekly index of marketing costs is preferred, but development of such an index for specific markets is difficult and would add little, given the aggregate nature of available data.

Calculation of estimated consumer surplus under alternative marketing patterns provides a measure of their impact on consumers. To simplify the calculation, we assume a linear demand curve with a constant slope and an intercept that changes by week, and a weekly supply curve that is perfectly inelastic. Weekly consumer surplus is summed over the fifty-two-week marketing season to derive estimated annual consumer surplus under the marketing alternatives. Calculations are based on the equation:

$$(2) \qquad CS = \sum_{t=1}^{52} \frac{1}{2} (a_t - PR_t) Q_t,$$

where CS is the annual estimate of consumer surplus, t is the week of the marketing year, a_t is the estimated weekly intercept in the price dependent retail demand curve, PR_t is the estimated weekly retail price, and Q_t is the weekly quantity of fresh lemon sales.

Estimated Demand and Margin Relationships

Estimation of the demand relationships necessary to evaluate alternative hypotheses related to the change in fresh lemon marketing patterns requires a number of decisions on the model utilized. The first problem was to choose the best method to estimate seasonality of demand. Earlier work indicated that seasonal demand shifts for fresh lemons involved shifts in the intercept rather than changes in the slope of the demand curve (Pick and Carman). This narrowed the choice; the final decision to utilize weekly dummy variables to estimate the shifts in demand over the marketing year was based on the straightforward nature of the estimating equation and the ease of using estimated results in evaluating the hypotheses.

A second decision involved the variables to include in the inverse demand equation. The equation specification from the earlier weekly demand study (Carman and Pick) was followed (average price = function of quantity of fresh shipments, income, lagged average price, a zero–one shifter for the 1985–86 marketing year, and seasonal shift variables). Use of the partial adjustment model was based on an observed stickiness of FOB prices. The zero–one variable for the 1985–86 marketing year was included to capture the possible structural impact of not using the weekly prorate feature of the marketing order. Earlier work indicated that 1985–86 prices were below the level expected for the weekly quantities marketed. A second zero–one variable was added to isolate the impact of revised price reporting procedures followed by the Lemon Administrative Committee beginning with the 1986–87 marketing year.

The weekly price equation, as specified above, was estimated by ordinary least squares (OLS) using data for the period 1974–75 through 1986–87. The Yule-Walker method was used to correct for autocorrelation after the Durbin h-statistic led to rejection of the hypothesis of zero autocorrelation at the 5% level. The estimated weekly demand equation for fresh lemons utilized for this study is as follows:

$$
\begin{aligned}

\end{aligned}
$$

$$R^2 = .95,$$

where the variables are defined as PF_t is average weekly FOB price of lemons for domestic fresh use, dollars per carton for all grades and sizes, deflated by the monthly consumer price index (1967 = 1.00); Q_t, weekly domestic fresh lemon shipments adjusted for population, carloads per million persons; Y_t, per capita real personal income (monthly total personal income, in billion dollars) deflated by the consumer price index and divided by population, in million persons; $D86$, dummy variable for the 1986 crop year to measure the possible impact of changed buyer and seller behavior in the absence of weekly prorate (1 for 1985–86, 0 otherwise); $D87$, dummy variable for the 1987 crop year to measure the possible impact of revised price reporting and recording procedures by the LAC (1 for 1986–87, 0 otherwise); DWK_t are weekly dummy variables, which have a value of one for week t and zero otherwise, included to measure weekly shifts in the demand for fresh lemons [week one is the first week of August (the first week of the marketing year which runs from August through July); the base week (week 52) is the last week of July, which is the last week of the marketing year], the estimated weekly dummy coefficients are presented in table 1; and t-statistics are in parentheses.

Each of the estimated coefficients for weekly shipments, income and lagged price has the expected sign and all are statistically significant at the 5% level with most being significant at the 1% level (one-tailed test). The two dummy variables, $D86$ and $D87$, included to capture the structural effects of operating without prorate during the 1985–86 marketing year and revised price reporting procedures during the 1986–87 marketing year, each have a significant negative coefficient. Average weekly shipments increased during 1985–86 when prorate was not utilized and increased shipments are associated with decreased prices.[2] However, the negative coefficient on $D86$ indicates that weekly prices decreased in the absence of prorate, even after allowing for increased shipments. The reduced price during 1986 could be explained by factors such as pricing behavior and the exercise of market power by large buyers or by a change in market conditions not accounted for by the model.

The pattern of weekly demand during the estimation period, as given by the coefficients reported in table 1, is plotted in figure 2. It is a

[2] The variable for sales and $D86$ are not independent. Previous work indicates that sales increased an average of approximately 13 carloads per week during the period when prorate was not used (Carman and Pick).

coincidence that the last week of the marketing year (the last week of July), which was used as the base week, was the week with highest demand. Thus, each of the estimated coefficients has a negative sign. Note that the average of the fifty-two weekly demand shifters is −.38; the price in the last week of July (the base week) is \$.38 per carton above the average for the year, other factors equal. The estimated price equation for each week during the marketing year can be derived by substituting the relevant coefficient from table 1 for DWK_t in equation (3).

Asymmetric Marketing Margins

A choice of the functional form for the marketing margin from among the several alternatives was based on examining the four hypotheses. The form of the FOB-to-retail margin for fresh

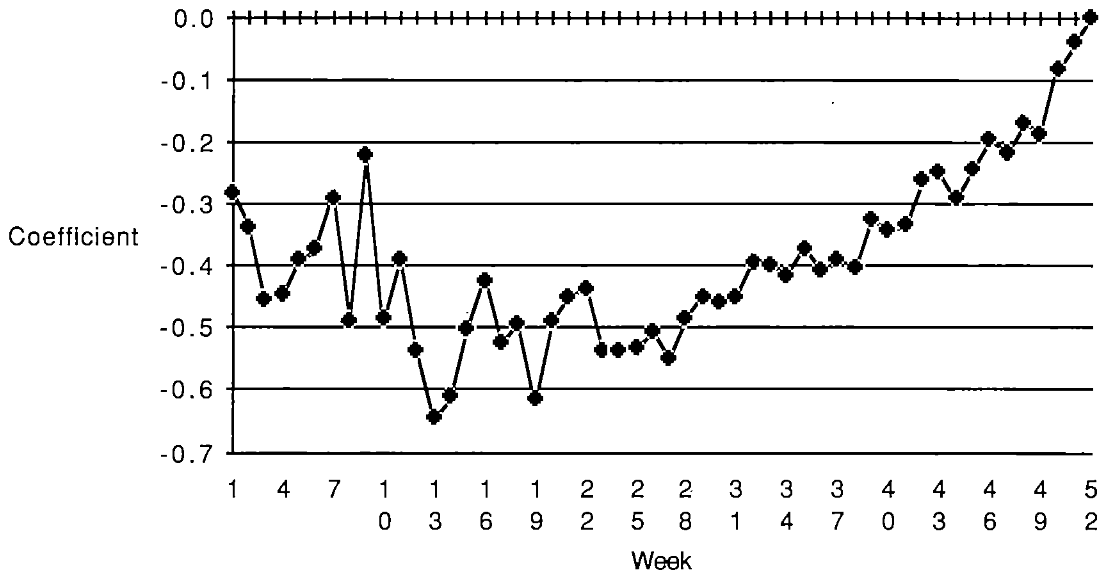

Figure 2. Estimated coefficients for the weekly demand shifter as reported in table 1

lemons has not been firmly established, but recent research on a limited data set supports the existence of asymmetric margins in some important markets. The impacts of a constant margin, a percentage margin, or a margin with both constant and percentage components are quite predictable and are of limited use in examining the hypothesis (III) that the LAC was responding to pressure from marketing middlemen. A constant dollar margin provides the same total revenue to middlemen regardless of the sales pattern; a percentage margin or a margin with percentage components will be maximized with a sales pattern which maximizes average FOB price. Thus, producer and middlemen interests coincide with the latter two margin types. With an asymmetric margin, however, price variability may have quite different impacts on producers and middlemen. For this reason, an asymmetric margin relationship was chosen.

Asymmetric marketing margin relationships for fresh lemons in four retail markets have been investigated (Karrenbrock, Pick, and Carman). Estimated coefficients indicated that retail prices responded more to FOB price increases than to decreases in each of the markets. The FOB-retail price relationship for the Denver market will be used to illustrate the implications of different orderly marketing policies on FOB-level returns and consumer expenditures for a given total quantity of fresh lemon sales. Because of a lack of aggregate marketing cost data for all fresh lemon sales, it is difficult to determine the degree to which the Denver margin relationship represents the total United States. The Denver margin equation was initially estimated using OLS, but the Durbin-Watson statistic adjusted for no intercept indicated the presence of autocorrelation. The generalized least squares method, in which the OLS residuals are used to estimate the covariance matrix, was then used to correct for autocorrelation. The margin relationship estimated for the Denver retail market, based on retail price data for forty-six weeks beginning 3 February 1985, was

$$\text{(4)} \quad PR_t = \underset{(5.96)}{1.49PFU_t} + \underset{(4.78)}{0.86PFD_t} - \underset{(-0.55)}{0.06T} \qquad R^2 = .88,$$

where the values in parentheses are t-statistics. The F-statistic for the test that $b_0 = b_1$ was significant at the 5% level, indicating that retail lemon prices in the Denver market responded more to FOB price increases than they did to FOB price decreases during the observation period. Calculated elasticities of price transmission (mean values) based on equation (4) were 0.55 for FOB price increases and 0.32 for FOB price decreases. The estimated coefficient on T, included to measure any systematic changes in marketing costs, was negative but not significantly different than zero. Thus, one can conclude that there was no evidence of a change (either increase or decrease) in marketing costs for the Denver market during the period of analysis.

The major components in the margin between the packinghouse and farm prices are picking, transportation, and packing. Average picking and transportation charges are similar from district to district, but packing charges vary because of storage practices and capacity utilization. Average margins used for this study by lemon production district are as follows: District 1 (Northern California), \$3.70 per carton; District 2 (Southern California), \$4.57 per carton; and District 3 (California Desert and Arizona), \$3.64 per carton. These margins were from sample averages of actual margins for the 1986–87 marketing year. The weekly margin was calculated as a weighted average of district shipments. Seasonal variation in the relative importance of each district results in a weekly change in average industry margins.

A Comparison of Marketing Alternatives

Estimated weekly price and margin relationships presented above are used to evaluate the impact of different sales patterns on total revenue at the FOB and on-tree levels and on annual consumer expenditures for 1986–87 fresh lemon sales. Domestic fresh market lemon sales totalled 15,732 carloads during the 1986–87 marketing year.[3] Four weekly sales patterns for total sales of 15,732 carloads will be evaluated: (*a*) actual weekly sales for the 1986–87 marketing year, (*b*) constant sales of 302.5 carloads per week for each week during the marketing year, (*c*) weekly sales varying to maintain a constant real FOB price of \$3.42 per carton (nominal price of \$11.44 per carton with total sales of 15,732 carloads), and (*d*) weekly sales which approximate the pattern to maximize total revenue at the FOB level (again totalling 15,732 carloads). Derivation of an approximate revenue-maximizing sales pattern with a total quantity constraint

[3] A carload is 1,000 cartons with a net weight of 38 pounds per carton.

proceeded in two steps. First, weekly sales necessary to yield a long-run price flexibility of demand equal to one were calculated (yielding a total of just over 18,000 carloads). Then these weekly quantities were reduced proportionately to the constraint of 15,732 carloads to maintain equal marginal revenues for each week during the marketing year.

Sales by four-week periods as a percentage of total 1986–87 sales for three of the alternatives (actual sales, constant price, and approximate revenue maximization) are shown in figure 3. Sales for constant 302.5 carloads per week would total approximately 7.7% for each four-week period. The constant price alternative has very low sales during the November through January period and very high sales June–July, compared with other weekly quantity allocations. It is unlikely that producers in Districts one and three would support such low sales during their peak production period and sufficient quantities of high grade lemons might not be available during some years to satisfy the June–July sales allocation. Other allocations would require relatively little change from recent actual sales and are feasible.

Calculation of total revenues at the FOB, retail, and farm levels for each of the alternative sales patterns proceeded in a series of steps. First, the estimated FOB price equation was used to calculate real FOB prices for each sales pattern (including actual sales) and these real prices wer then converted to nominal 1986–87 prices. Th estimated FOB to retail marketing margin wa added to the nominal FOB price to obtain estimated weekly retail prices. Then, estimate 1986–87 weighted average weekly packing transportation, and picking charges were subtracted from FOB prices to obtain weekly farm-level prices. Finally, the estimated weekly price at the farm, FOB, and retail levels were multiplied by weekly sales for each of the four alternative sales patterns to obtain total revenue and these were summed over the 52 weeks o the 1986–87 marketing year. These calculate total revenues are presented in table 2.

Examination of estimated total revenues at th farm, FOB, and retail levels in the fresh lemo marketing system reveals some interesting relationships (table 2). First, the particular orderl marketing strategy followed can have an important impact on producer returns, whethe measured at the FOB or on-tree level. A strategy of constant sales in the face of seasona variation in demand for fresh lemons resulted i much lower total revenue at the farm and FO levels than did a strategy of varying the weekl quantity to maintain a stable price. As shown i table 2, the constant price strategy increased total returns at the farm and FOB levels by $20.9 million (23%) and $23.0 million (15%), respec-

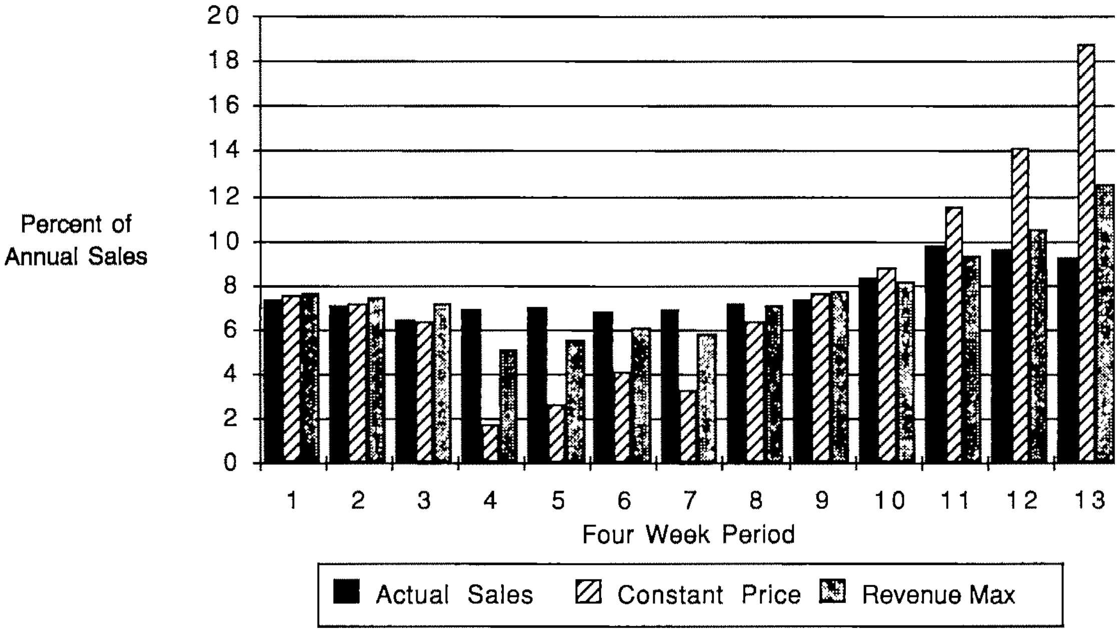

Figure 3. Four-week period percentages of annual sales by sales pattern, 1986–87 marketing year

Table 2. Estimated Total Revenues at Farm, FOB, and Retail Levels for 1986–87 Fresh Lemon Sales with Associated Margins: Four Alternative Weekly Sales Patterns

Marketing Strategy	Estimated Total Revenue at Different Levels in System				
	Farm	Margin	FOB	Margin	Retail
	($ mill.)				
Actual sales	94.6	66.1	160.7	422.4	583.1
Constant sales	92.2	65.7	157.9	425.9	583.8
Constant price	113.9	67.0	180.9	395.7	576.6
Revenue max	128.8	66.6	195.4	409.4	604.8

tively, over the constant weekly sales strategy. An FOB revenue-maximizing sales pattern further increased revenues by $15.7 million and $14.5 million at the farm and FOB levels, respectively, over the constant price strategy. Actual industry weekly sales resulted in farm-level and FOB total revenues only slightly greater than the constant sales strategy, and total revenues were significantly less than from a constant price strategy.

The FOB-to-retail margins vary in response to the marketing strategy followed. The constant sales strategy, which results in variable prices, yields the highest FOB-to-retail margin totalling $425.9 million, while the constant price strategy results in a margin of $395.7 million (calculated from table 2). The margin for the actual sales pattern of $422.4 million is very close to that resulting from a constant sales strategy, while the revenue-maximizing strategy provides a margin of $409.4, which is midway between the high and low margins. With an asymmetric margin, middlemen clearly benefit from movement away from varying weekly sales with constant prices and toward constant weekly sales with variable prices. If the FOB-to-retail margin was a percentage or had a percentage component, then middlemen would prefer the sales pattern yielding the highest average FOB price (the revenue-maximizing pattern).

The economic results of various marketing strategies may vary by production district because of different seasonal production patterns. The weekly percentages of actual weekly sales for each district were applied to the total weekly sales for each sales pattern to investigate the impact of each sales strategy on total revenue at the producer level. Comparison of the constant price and constant weekly sales strategies in table 3 indicates that Districts 1 and 2 producers would have enjoyed the largest returns with a constant price strategy but District 3 producers would have preferred the constant quantity strategy. In fact, District 3 estimated total revenue from the constant quantity strategy was greater than from the sales strategy which would have approximately maximized total industry sales revenue from sales of 15,732 carloads during the 1986–87 marketing year.

Consumer surplus was calculated for a linear retail demand curve based on the estimated FOB demand plus the estimated marketing margin. Estimated annual consumer surplus for 1986–87 fresh lemon sales totaled $93.6 million for the constant weekly sales alternative (302.5 carloads per week). This was increased by 24% to $115.8 million by the marketing strategy based on maintaining a constant weekly FOB price of $11.44 per carton by varying sales in line with seasonal demand. Consumer surplus was decreased by 8% to $86.4 million by a sales pattern designed to maximize total FOB-level revenues. The actual pattern of weekly sales resulted in estimated consumer surplus of $97.9 million. It is interesting, but not surprising, that the stable price marketing alternative resulted in higher consumer surplus than did constant weekly shipments, even though total retail revenue (table 2) was higher with constant prices. Massell demonstrated a similar result with his integration of

Table 3. Estimated Total Farm-Level Revenue by Production District for 1986–87 Fresh Lemon Sales: Four Alternative Weekly Sales Patterns

Marketing Strategy	Estimated Total Farm Revenue by Production District		
	District 1	District 2	District 3
	($ mill.)		
Actual sales	10.883	61.453	22.226
Constant sales	10.667	57.134	24.435
Constant price	12.339	80.627	20.907
Revenue max	13.210	92.699	22.874

the Waugh-Oi results on the effects of price stabilization on consumer and producer surplus.

Who Benefits?

Market allocations for California–Arizona fresh lemons changed rather abruptly from one that resulted in relatively stable prices over the marketing year to one that resulted in variable prices. Because the lemon industry regulates weekly fresh lemon shipments under a marketing order designed to improve producer returns, one would expect the change in marketing policy to benefit producers as a group. Our estimates indicate, however, that this was not the case. Total industry returns at the producer level are clearly much less for a marketing strategy that emphasizes stability of shipments as opposed to price stability. Following is a discussion of the hypothesized reasons for the change in lemon marketing patterns.

Hypothesis I

Concerns about the effects of marketing orders on inflation and on consumers received considerable publicity during the 1970s. Federal Trade Commission and Justice Department officials charged that marketing orders raised the prices of regulated commodities, and that consumers were ignored in the establishment of marketing order policies. The hypothesis that the LAC was responding to public pressure or to pressure from the secretary of agriculture, who is charged with protecting the interests of consumers and the public (as well as producers), is not supported by our estimates. Consumers are made worse off by stable sales in the face of seasonal demand. They pay more for a given quantity of lemons and also have a significant reduction in consumer surplus. If the LAC was responding to pressure from administrative agencies, the response would have more likely been evidenced by increased total fresh market shipments rather than a change in seasonal shipments. Total fresh lemon shipments, however, remained quite stable during the 1970s.

Hypothesis II

Support for the hypothesis that the LAC was attempting to improve producer returns is mixed. Estimates in this study clearly indicate that industry-wide total returns to producers are reduced when moving from relatively stable prices to relatively stable shipments for a given total quantity of fresh lemons. It is likely, however, that individual producers improved their returns because of the seasonal nature of production. District 3 producers appear to have improved the percentage of their crop going to the domestic fresh market (and their average returns) relative to the other two districts. As shown in table 3, District 3 producers realized the largest estimated total revenue from the marketing strategy of constant weekly sales, and the actual 1986–87 weekly sales pattern yielded only slightly lower total revenue than did the industry revenue-maximizing sales pattern for a crop of 15,732 carloads. Estimates in table 3 indicate that Districts 1 and 2 producers would have been much better off with a constant price strategy than with the actual sales pattern during the 1986–87 marketing year. Districts 1 and 2 gains when moving from the actual sales pattern to a strategy of maintaining constant prices ($20.5 million) were several times the loss for District 3 (−$1.3 million). District 3 typically had three out of the eight grower members on the LAC after the 1971 marketing year. Thus, they would have needed support from other members of the LAC to change the sales pattern. Such support may have been relatively easy to secure during the weeks when District 3 accounted for the majority of lemon supplies.

Changing production patterns, which led to the change in LAC membership, may have influenced weekly prorate allocations. District 2 supplies most of the lemons marketed during May, June, and July, and its share of industry production decreased significantly from the earlier to the later period. This changing availability of seasonal supplies may have been reflected in fresh market allocations. Such a change is difficult to verify because the weekly prorate was used during most weeks during most marketing years, and, presumably, limited the quantity of lemons sold on the fresh market when used.

Hypothesis III

Given the assumption of asymmetric marketing margins, middlemen clearly gained from movement toward a marketing pattern that resulted in more variable prices. This lends support to the hypothesis that the LAC may have responded to pressure from marketing middlemen. However, the manner of influence is not clear. The thir-

teen-member LAC is composed of eight growers, four handlers, and a nonindustry member. The interests of producers and handlers appear similar based on a ranking of returns in table 2. In addition, because at least one of the handler members is from a marketing cooperative, handler interests should closely coincide with those of producers. Middlemen could have offered several reasons to justify a policy movement toward stable shipments. For production-oriented handlers, uniform week-to-week shipments facilitate capacity planning, labor scheduling, ordering materials, budgeting, and shipping. Stable shipments can also help to maintain retail shelf space and service large institutional buyers. This is pure speculation, however, since we have no evidence that middlemen advanced any such arguments.

Hypothesis IV

There was significant growth in the export market for lemons, beginning in 1971–72, especially the Japanese market. Weekly quantities of fresh lemons exported were examined for the 1961–72 and 1974–87 periods, but weekly export prices were not reported by the LAC.[4] Comparison of the weekly pattern of exports with the weekly pattern of domestic fresh sales reveals a similar pattern for each of the two periods. Exports were much higher in the May through September period than in other months during the 1961–72 period, just as were domestic sales. Exports increased throughout the year for the 1974–87 period and seasonal changes became much smaller, with the seasonal pattern of domestic sales and exports again demonstrating a close match. Thus, there was a change toward greater stability of export sales as well as domestic sales 1974–87, and we presume that export prices also became more variable.

Concluding Comments

Various marketing policies can be characterized as orderly marketing but with quite different results for producers, middlemen, and consumers. Estimated returns for California–Arizona fresh lemon sales indicate that constant week-to-week sales may not be consistent with a goal of increasing total returns to producers through use of a prorate program. With varying seasonal demand, a marketing pattern which increased sales when demand was increasing and decreased sales when demand decreased improved total crop returns over those observed with stable sales. The polar case of maintaining a constant FOB price from week to week improved total producer returns over the constant sales case by more than $20 million at the farm level. Middlemen returns, as measured by the marketing margin, varied with the seasonal sales pattern but were highest with constant weekly sales.

Calculated consumer surplus indicated that consumer welfare was greater with a constant average price and varying sales than with constant weekly sales. Thus, given a choice between constant sales or constant prices as an orderly marketing strategy for lemons, both consumers and producers, as a group, would prefer constant prices with quantities shifting in line with seasonal demand. Producers, as a group, can increase their returns by moving away from a constant price strategy and toward a revenue-maximizing sales pattern, but such a move involves reductions in consumer surplus. The term orderly marketing can be interpreted in different ways and can be used to justify either stable sales or stable prices. As shown, the particular marketing policy followed has quite different economic implications for lemon producers (individually and as a group), middlemen, and consumers.

The abrupt and distinct change in lemon marketing patterns that occurred during the mid-1970s is not easily explained by a single hypothesis from among those posed. The timing of the change was related to changes in the relative importance of the three production districts, to changes in the membership of the LAC (which was related to changing production), and to increased lemon exports. The recent pattern of relatively stable sales, when compared with more variable sales, appears to have reduced total returns to District 1 and 2 producers and decreased total consumer surplus while increasing total revenues to District 3 producers and middlemen. Based on our review of the evidence, the changed marketing pattern could not be attributed to any pressure designed to benefit consumers; neither did it appear to result from an expanding export market for fresh lemons. While marketing middlemen may have benefitted from the change, there is little to indicate that they took actions leading to the change.

At this point, the most plausible explanation

[4] Average returns for domestic fresh and export lemon sales are highly correlated on an annual basis, with export returns slightly below those for domestic fresh sales (Kinney et al., pp. 19–20).

for the change in sales patterns relates to regional changes in production and changes in LAC membership. With increased production in Districts 1 and 3, the availability of fresh lemons increased during the period from October through April relative to May through September. The lemon marketing order specifies that the LAC shall give due consideration to the quantity of lemons in storage and lemons on hand (as well as factors affecting demand) when making a recommendation for regulation of shipments. Thus, changing seasonal production patterns would have provided pressure for changing fresh market allocation patterns. At the same time, new LAC members from Districts 1 and 3 might have attempted to increase their share of fresh market sales to increase returns for producers in their districts. This combination of factors appears to account for the rather abrupt change in seasonal marketing patterns for fresh lemons.

The Strategic Role of Supermarket Buyer Intermediaries in New Product Selection: Implications for Systemwide Efficiency

Edward W. McLaughlin and Vithala R. Rao

Based on logistic regression models that describe the accept/reject decisions of supermarket buyers for new products and market performance of accepted products, the implications for systemwide efficiency of decision making by channel intermediaries are analyzed. The statistical models perform very well. The results point to areas where systemwide performance may be enhanced regarding the allocation of new product development resources. For example, the system may be potentially more efficient if manufacturers reallocate the promotional allowances directed to the retail trade. Better prediction by retail buyers of ultimate product preference by their consumers is likely to increase both firm and system efficiency.

Key words: efficiency, logistic regression, marketing strategy, new products, performance.

Although the management and organizational theory literature is rich in its treatment of internal firm behavior, relatively little of this work has penetrated mainstream economic analysis. This situation is part of the general neglect by economists and agricultural economists of management strategy and conduct, as pointed out by Marion, Leibenstein, Shaffer, among others. To the extent that economic behavior has been studied, however, it has been through the work of industrial organization (IO) economists and, specifically, their work with the structure-conduct-performance (S-C-P) paradigm (e.g., Scherer 1979, 1980). However, Henderson and Marion have noted that IO theory rarely explicitly considers the firm decision environment, either at manufacturer or distributor levels. Recently, several researchers (e.g., Westgren and Cook, Rogers and Caswell) have identified internal firm decision-making and strategic behavior as a high priority research area. Ultimately, if improvements in systemwide efficiency are to be achieved, a better understanding of internal firm decision making is required.

Edward McLaughlin is an associate professor of Food Distribution and Marketing in the Department of Agricultural Economics, and Vithala R. Rao is a professor of marketing and quantitative methods at the Johnson Graduate School of Management, both at Cornell University.

The Research Context

Increase in new grocery product introductions (alternatively, product proliferation) is an economic phenomenon where a better understanding of firm behavior (conduct) is essential to improving systemwide efficiency. Product proliferation has been widely cited as one of the major modes of competitive conduct by leading grocery manufacturers (Padberg and Westgren, Connor, Zellner). In 1988, estimates of the number of new products, including both fundamentally new products derived from new technologies and line extensions (e.g., new flavors or packages sizes) ranged as high as 10,558 (Gorman). This number is more than twice the 1970–81 annual average (Gorman). The resources required to support this yearly influx of new products are enormous for the entire grocery system. Although aggregate data on costs of new product introductions are not available, selected references on individual product introductions suggest that industry-wide totals are staggering. *Fortune,* for example, reports a total development expenditure of $1.5 billion by the Proctor and Gamble Company to introduce a single product, its Ultra-Pamper diaper, to U.S. supermarkets; $1 billion of this was spent on advertising alone.

Although overall retail store sizes have continued to grow, the relative space allocated to dry groceries has been constant or declining over the last five years (*Progressive Grocer,* Oct. 1987). Wholesale and retail companies simply do not have physical or financial capacity to accommodate all of the the new products, so choices have to be made. Because many products, probably the majority (*Progressive Grocer,* Nov. 1987), do not gain entry into the supermarket system, large economic losses are incurred by manufacturers as well as intermediary firms.

To maximize both distributive efficiency and the probability of new product acceptance, manufacturers require an intimate knowledge of buyers' behavior, not just at consumer levels but at the pivotal channel intermediary (i.e., supermarket buyer) levels as well. Economic theory suggests that manufacturers should make allocations of a predetermined budget for a new product to various components of the new product's marketing plan to equalize marginal returns. To exercise this optimality criterion, manufacturers need better information regarding the characteristics of new products that are most important to buyers in their accept/reject decisions. Further, information is needed on those characteristics of products that are likely to assure consumer acceptance in the marketplace.

Against this background, this paper develops logistic regression models to formalize the channel intermediary's conduct and decision processes regarding new product introductions by manufacturers. The effects of various components of manufacturers' conduct (e.g., marketing strategies) on new product selection decisions are estimated. Further, the status of accepted new products after a period of time was also examined to understand the differences between the intermediary's acceptance and marketplace acceptance. The implications of these analyses for systemwide efficiency are discussed.

Literature Review

Past research of new product introductions may be separated into those with a public policy orientation and those with a managerial perspective. In the former group, the common conceptual theme has been the S-C-P paradigm using secondary sources of data. Some relevant studies in this stream are those by Adams and Yellen, who studied the similarity of new products; Schmalensee, who identified new product proliferation as an explicit manufacturer strategy to erect entry barriers; and Scherer, who estimated the welfare effects of new product introductions. Conner has investigated relationships between manufacturer market structure and the number of new products (for elaboration of these studies, see Connor et al.) As in much of the structure-performance literature, the emphasis on the conduct dimension in these studies, especially of the intermediary-buyer, is minimal.

However, a valuable strain of literature examines new product acceptance from a strategic managerial perspective. Grashof, for example, found that product newness was the most important criterion in a single product category, dog food, when attempting to evaluate the effect of hypothetical product mix on the operating results of supermarkets. Heeler, Kearney, and Mehaffey, in studying a limited data base, concluded that the procurement function could be made more efficient by eliminating those products that did not merit marginal evaluation. Montgomery modeled buyer reaction to hypothetical products; and, while certain of his findings were consistent with a priori expectations—e.g., advertising support was a significant predictor of product acceptability, he pointed to the cumbersome nature of his analytical models for larger data sets.

Thus, past efforts to evaluate new product introductions have relied either on secondary data involving limited numbers of categories, simulated experiments, strictly theoretical approaches, or buyer reaction to hypothetical products. Only modest attempts have been made to investigate the intermediary conduct of the supermarket headquarters buyer. Yet, the strategic decisions made by this link between manufacturer and consumer are key to developing total system efficiency improvement. Finally, the most recent empirical studies (Scherer and Connor) were both conducted on data collected from the 1970s. Given the surge of new products over the past decade and their increasing economic importance, research on this important strategic activity using primary data is required.

Buyer-Seller Conduct

Although various typologies of new products may be cited (e.g., Connor), new products in this paper refer to all items new to the channel intermediary including new flavors, new sizes, and new brands. National brand manufacturers cite

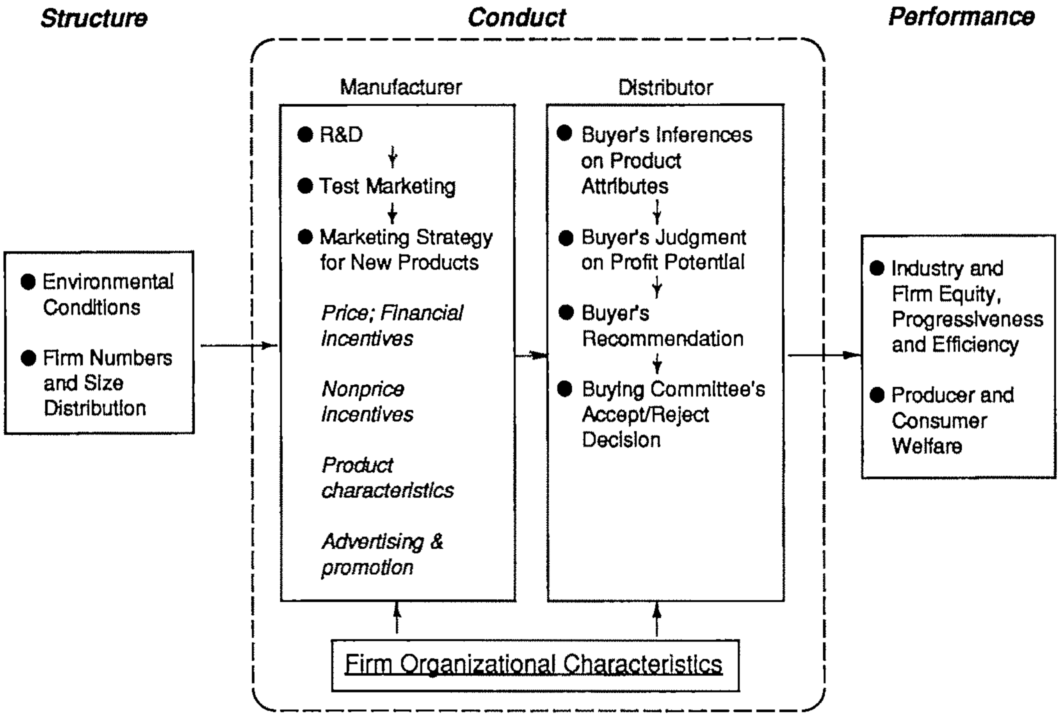
a number of reasons to justify the proliferation of new products, including maintaining interest of channel intermediaries and consumers, extending an item to an adjacent product-space to attract incremental business, taking advantage of new technologies and changes in consumer demand, countering competitive thrusts or preempt competition, transforming a commodity to a higher margin value-added item, and partially ensuring against high new product failure rates.

Despite the key role played by new products in manufacturer marketing strategies, their proliferation imposes considerable costs on other channel members (e.g., wholesalers and retailers) and consumers. Retail organizations, for example, are often attracted to new products by the lure of additional profit opportunities. However, they must also face substantial costs associated with new products. Included are personnel costs in evaluating new products (Hamm), costs of entry and maintenance of new data, and other costs associated with inventory control and handling, specialized wholesale and retail space requirements, and production of shelf signs. Finally, new products may impose substantial direct and indirect costs on consumers. These latter costs come in the form of higher search and information processing costs (e.g., potential confusion regarding new products' characteristics and availability) and higher prices for most new products.

The above discussion points to the importance of the channel intermediary's decision-making process to the performance of the total grocery system. Yet, past research has not shed much light on whether, or in what ways, the intermediary's role enhances or inhibits efficiency. As manufacturers develop new products at a more rapid rate than intermediaries can accommodate them, neoclassical notions of consumer sovereignty initiating efficient decisions may break down if the intermediary becomes the arbiter of consumer choice. Moreover, manufacturer inducements, such as couponing, billing allowances, and free goods, may be more important to the buyer then inherent product quality. These propositions are critical to grocery system resource allocation and efficiency.

The Supermarket Intermediary's Initial Acceptance Model

The conceptual model guiding our analysis of the behavior of the supermarket buyer to accept or reject a new product is presented in figure 1.



Note: Feedback loops not shown here.

Figure 1. Conceptual approach to new product conduct

This approach elaborates the often neglected "black box" or conduct dimension of manufacturer-distributor exchanges, specifically relating to new product behavior. Scherer (1980) suggested that conduct has not received adequate research attention primarily due to the difficulty of quantification and the lack of researcher access to the requisite data. This study attempts to remedy both of these traditional constraints.

Our conduct model implies that a new product's acceptance and, ultimately, system efficiency and performance is a function first of manufacturer and distributor structure (e.g., firm numbers and size distribution), including their organizational characteristics (e.g., chain versus wholesaler), and subsequently of the strategies and decision-making procedures of both sets of firms. For example, subsequent to the generation of a new product idea, a prototype is developed and modified through various phases of R&D activity and consumer research before an initial marketing strategy for the item is established by the manufacturer. The new item may then be presented to the buyer/intermediary. Effectively, the buyer evaluates the new product's likely demand and profit potential (modeling of buyer's judged profit potential has been reported in McLaughlin and Rao) based on the information (e.g., marketing strategy) presented by the manufacturer. The strategy variables typically include price and other financial incentives (e.g., margin structure, credit, forward-buy provisions), promotional factors (e.g., coupons, in-store signage), advertising campaigns, various aspects (e.g., taste, appearance) of the new product and, often, certain nonprice incentives (e.g., free goods, delivery scheduling, slotting allowances).

A number of opportunities for contact and negotiation between manufacturer and distributor occur during this process:[1] distributors may at times initiate the idea of developing a new item with a manufacturer based on perceived market demand; manufacturers sometimes make use of buyer judgment as a proxy for a test market or often share results of any preliminary test marketing for retailer reaction; manufacturers frequently alter certain marketing strategy variables (especially nonprice incentives) based upon the suggestions made by the retailers. Thus, our conceptual model depicts the critical transmittal of information vertically, between manufacturer and retailer (intermediary), as well as the decision making within each firm.

Finally, often after repeated contacts with the supplier, the buyer makes a recommendation to a buying committee. This committee normally consists of senior executives constituted to represent the firm's diverse interests. The buying committee, nearly always acting in accordance with the buyer's recommendation, makes the final decision. This paper models the interaction between manufacturer and retailer (intermediary) that leads to final accept/reject decision.

After review of the above literature and numerous meetings with the participating intermediary, a large number of factors was identified that appear to play influential roles in manufacturers' new product introductions to distributors. In table 1, the relevant variables are grouped into four categories: financial, competition, marketing strategy, and other. These variables are, in effect, both the objective and subjective measures of conduct—the give-and-take negotiation process—between manufacturer and distributor suggested in figure 1.[2] Further, we have hypothesized the direction of influence of each variable on the intermediary's decision to accept a new product; the reasoning behind most of those hypotheses is straightforward. However, brief explanations are provided below.

Of the financial factors, the gross margin and profit variables are hypothesized, with some uncertainty, to have a weakly positive effect on product acceptance. Gross margin may be set at high levels to cover required, but perhaps burdensome, tasks to be performed by retailers. In these cases, high gross margins may negatively influence new product acceptance because a high gross margin may not yield a high profit. Similarly, a high profit level may indicate a high price that could dampen consumer demand making the product less acceptable to distributors. The final financial factor, the opportunity cost variable, is expected to have a negative influence on buyer's likelihood to accept a new product the greater the minimum dollars required to order the product.

Competition was broken into two parts: firms and brands. The "firms" variable measures the number of competing distributor firms which al-

[1] Distributor is a term used interchangeably to refer to both wholesale and retail intermediaries. As a chain store organization, the intermediary participating in the empirical part of this research performs both these functions.

[2] Our specification of this conduct model may in fact capture the effects of certain structural variables. For example, the effect of size of manufacturer is partially accounted for by the measures of vendor effort and several of the terms of trade variables.

Table 1. Variables, Operationalization, Specific Measures, and Hypotheses

Category	Variable	Measure(s)	Hypothesized Influence on Buying Decision
Financial	Gross margin	Percentage gross margin	Positive (?)
	Profit	$ profit per cu. ft. of shelf volume	Positive (?)
	Opportunity cost	Dollars needed to meet min. order quantity	Negative
Competition	Firms	Actual buyer determination of numbers of firms and brands	Positive
	Brands		Negative
Marketing strategy	Product uniqueness (quality and package)	Buyer judgments on 0–10 scales (sum)	Positive
	Vendor effort	Buyer judgments on 0–10 scales (sum)	Positive
	Marketing support	Three categories—none, partial, and high support	Positive
	Term of trade	Presence or absence of off-invoice, slotting allowances, bill back and free cases	Positive or negative
	Price	Two dummy variables for low and medium prices	Positive (?)
Other	Category growth	Index of buyer judgments on 0–10 scales	Positive
	Synergy	Whether item is a member of a family (0,1)	Negative

ready carry this item, and the "brands" variable measures the number of competing manufacturer brands carried by the distributor. We hypothesized a positive relationship between the firms variable and buyer acceptance. In essence, a vigilant buyer is likely to be favorably influenced by a positive evaluation of the new item by a competing firm. On the other hand, we hypothesized that the likelihood of buyer acceptance decreased as the number of existing national brands and private label products that competed for limited shelf space with this item increased.

We developed a series of measures to describe manufacturers marketing strategies. Generally, we expected positive relationships with these strategy variables under the control of the vendor. For example, we expected that, as the score on product uniqueness (that is, a composite variable combining buyer judgments of product quality, performance, and package design) increased, buyers would be more likely to accept the product. Similarly, we expected as marketing support increased from "none" (no T.V. or coupons) to "partial" (either T.V. or coupons) to "high" (T.V. and coupons) that buyer acceptance would also increase. The reasoning for the other strategy variables was similar except for bill back provisions. Many retailers find it cumbersome to "bill back" the manufacturer for allowances after having complied with certain performance requirements. The transaction costs of the paperwork are not trivial. Hence, we hypothesized that this particular term of trade would negatively influence acceptance.

Finally, new products in fast growing product categories are expected to be accepted with higher probabilities by channel intermediaries. A new item's synergy, the association with a family of existing products, is hypothesized generally to reduce acceptance probability. The reasoning again was based on physical space limitation: intermediaries are less likely to add line extensions to existing products. However, the strength of this relationship naturally depends upon the distributor's prior experience with the parent line.

Since the choice variable is dichotomous (accept or reject), the acceptance probability for a new product can be modeled by the familiar logistic function:

$$(1) \qquad P_j = \frac{1}{1 + \exp(-\alpha - \underset{\sim}{\beta}'\underset{\sim}{X}_j)},$$

where P_j is the probability of acceptance of the jth item by the channel intermediary, $\underset{\sim}{X}_j$ is a ($p \times 1$) vector of descriptors measured for the jth item, $\underset{\sim}{\beta}$ is a ($p \times 1$) vector of parameters, and α is an intercept term.

The logistic regression model in equation (1) is estimated by maximum likelihood methods, using the LOGIST procedure developed by Walker and Duncan and implemented in the SAS package (Harrell).

Empirical Study

In accordance with the conceptual model of manufacturer-distributor conduct, data were collected from a large supermarket chain chosen to exemplify the typical organization for evaluating new products. The chain is publicly held, covers a large trading area with approximately 100 stores in the northeastern United States, and its 1988 sales approached $1 billion. The chain's headquarters region is frequently employed by manufacturers for test marketing because of the representativeness of its consumer profiles and market area. It is highly unlikely that any food manufacturer would bypass this firm in the introduction of a new product. Hence, although the model applies only to one company, the representativeness of the firm may permit a cautious generalization of the results to other market conditions.

Two types of primary data were collected from the chain: (*a*) vendor-supplied materials including product physical characteristics (e.g., case cubic dimensions), financial information (e.g., suggested retail price, gross margin), and promotional support (e.g., television ads, couponing), and (*b*) a one-page questionnaire completed by each buyer assessing his/her judgments of qualitative attributes (e.g., taste, quality, performance) for every new item. Several variables employed in the model were computed from the data (see table 1). The data were collected for about 2,000 products on a weekly basis from June 1986 to February 1987. These new items belonged to more than 25 product categories based on the retail trade classification system of *New Product News* (Gorman).

Intermediary's Acceptance Rates

The overall acceptance rate for new products presented to this chain was 29.0%. However, significant variation exists in the rates of acceptance by product category (e.g., at the extremes, 21% for canned foods to 61% for pet products) and by suggested retail price of the item (27% for items priced less than $1.00 to 39% for items over $2.00). Further, consistent with prior expectations, acceptance rate steadily grew as the levels of marketing or promotional support (television advertising and coupons) increased: 24% of products with no promotional support were accepted, 41% with limited support (either coupons or TV), and 46% with high levels (coupons and TV) of promotional support.

Some past studies (e.g., Connor) suggest that total promotional support is generally highly correlated with the size of the firm offering the new product to the channel. Additional data on manufacturer size, using total sales as a measure, were collected using the sources of Moody's industrial manuals, Standard and Poor's stock reports and Ward's directories. This effort yielded complete data for over 75% of the new products and over 80% of the firms involved. For the available data, the acceptance rate was 41.3% for firms with annual sales over $700 million, 28.6% for firms with sales between $2 million and $700 million, and 29.2% for firms with sales under $2 million. Thus, results from past studies were corroborated for the largest firm category but were less consistent for the smaller firm categories.

Analysis Method

Unfortunately, nearly 50% of the collected data were not analyzed in this model because some of the variables were incomplete. However, a sample of the product profiles from the incomplete data set was analyzed and was not significantly different from the profiles in the complete data set. The complete data were divided randomly into two subsamples for analysis and validation; the validation data constituted about one-third of the total sample. The major analysis consisted of building logistic regression models for all categories of items, for subgroups of items with several levels of marketing support, and for groups of items of different price ranges. Analyses for subgroups of items were conducted to account for the inherent heterogeneity among the various categories of products. In all of these models, the product category variations are accounted for by a set of dummy variables.

Results

The logistic regression model fits the data well. The predictive accuracy exceeds 78%, much higher than that expected by chance. Additionally, the model correctly predicted 72% of the decisions in the validation sample.

The estimated coefficients for the variables for the logistic model for the total analysis sample are shown in table 2. The model chi-square

Table 2. Results of Logistic Regression for Total Sample (Accept/Reject Decisions)

Group of Items Variable	All Items
Intercept	−5.47 (41.92)*[c]
Gross margin	−0.06 (10.30)*
Profit per shelf volume	0.004 (3.24)+
Opportunity cost	−0.001 (1.14)+
Number of competing firms	0.14 (11.72)*+
Number of competing brands	−0.03 (1.89)*
Product uniqueness (quality)	0.25 (18.03)*+
Vendor effort[a]	.03 (0.46)+
Terms of trade dummies:	
Off-invoice	−0.19 (0.70)
Slotting allowance	−0.43 (2.03)
Bill back	−0.93 (6.04)*+
Free cases	−0.22 (0.87)
Low-price dummy	−0.17 (0.30)
Medium-price dummy	0.02 (0.01)+
Expected category growth	0.68 (46.49)*+
Synergy dummy	−0.31 (2.01)+
Product category dummies[b]	(not shown)
Number of observations	687
Model Chi-square, D.F.	249.49, 23
P-Value	0.0

Note: Entries are coefficient and chi-square for each variable (with 1 d.f.).
[a] The marketing support variable is in this buyer judgmental variable.
[b] The relative differences on estimated acceptance probability of product categories are shown in table 4.
[c] Single asterisk indicates significant at 0.05 level; plus sign indicates sign of the coefficient is according to expectations.

is highly significant. Further, the coefficients of the majority of the variables are in the predicted direction. The variables of product uniqueness, expected category growth, and number of competing retail firms show postitive and significant effects. The variable bill-back terms of trade shows a negative and significant effect. These results are consistent with our hypotheses for the model. The only significant variable with a sign contrary to the hypotheses is gross margin for which we had hypothesized a weak positive relationship. This finding is consistent with similar results of Montgomery, however, who found a negative but not significant relationship between new product acceptance and gross margin. The only other variables that appear with contradictory signs were the remaining terms of trade factors, but their coefficients are not statistically significant.

Model Structure for Subgroups

The logistic model was also estimated for subgroups of items—by marketing support and by price. The model chi-square statistics are uniformly high. As could be expected, the classification accuracy (not shown here) improved for the various subgroups of items (resulting from greater homogeneity within a subgroup). For brevity, only the significant variables and their direction are shown in table 3 for these subgroup models.

The subgroup models revealed a number of differences from the overall model. First, for low-priced items, as the intensity of vendor effort and profit per shelf volume increase, the probability of acceptance increases. Second, for medium and high price items, gross margin, vendor effort, and profit per volume cease to have significant influences on the accept/reject decision; however, both product quality uniqueness and expected category growth show positive significant influences. In addition, the synergy dummy has a negative significant effect for high-priced items. Third, product uniqueness measure is the only significant variable common to both highly supported and unsupported items. For highly supported items, opportunity costs (negative), expected category growth (positive), and both price dummies (negative) are significant; while for unsupported items, gross margin (negative), number of competing firms (positive), and vendor effort (positive) are significant indicators.

Considerable variation occurs in the acceptance of new products by product category as presented in table 4. In the sample as a whole, empirical acceptance rates are much higher for the categories of candy and gum, sauces, etc., and snacks, crackers, and nuts. Table 4 also shows the estimated probabilities of new product acceptance for items comparable on all aspects but the product category for all items and for each subgroup of items. These estimates were calculated using a base of .33 for the "other" category, essentially to control for all aspects of the new item except the product category. Thus, they indicate the "true" differences among the product categories. These data show that for all items, household supplies and dairy foods have the lowest acceptance probabilities and items from

Table 3. Significant Variables for Logistic Regression for Selected Subgroups of Items (Accept/Reject Decisions)

Subgroup of Items	Significant Variables	Sign of Relationship	Number of Observations	Model Chi-Square; D-F, P-Value
Low-priced items ≤$1.00	Gross margin	−	237	90.61; 21
	Profit/shelf volume	+		0.0
	Vendor effort	+		
Medium-priced items $1.00–$2.00	Number of competing firms	+	289	128.06; 21
	Product uniqueness	+		0.0
	Slotting allowances	−		
	Bill back	−		
	Expected category growth	+		
High-priced items ≥$2.00	Number of competing firms	+	161	117.75; 21
	Product uniqueness	+		0.0
	Expected category growth	+		
	Synergy dummy	−		
Unsupported items	Gross margin	−	194	120.87, 23
	Number of competing firms	+		0.0
	Product uniqueness	+		
	Vendor effort	+		
Highly supported	Opportunity cost	−	155	95.61; 23
	Product uniqueness	+		0.0
	Low price dummy	−		
	Medium price dummy	−		
	Expected category growth	+		

Note: Price variable was described by three categories shown above, and dummy variables were used in the model for the low and medium categories.

the candy and gum group have the highest acceptances. The rankings of categories change when subgroups of items are examined. For example, for the highly supported items, dairy foods receive a much higher acceptance while candy and gum continue to enjoy highest acceptance. Other interesting differences include a nonmonotonic relationship between acceptance probability and price of the new item for such categories as frozen foods, canned foods and sauces, spices, etc.

Finally, the coefficients of the models by firm size (not shown here) reveal notable differences in the slotting allowance variable. This variable

Table 4. Product Category-Specific Probabilities in the Logistic Models of Accept/Reject Decisions

		Illustrative Acceptance Probabilities for Comparable Items for					
Product Categories	Empirical Acceptance Rate (%)	All Items	Unsupported Items	Highly Supported Items	Low-Priced Items	Medium-Priced Items	High-Priced Items
Frozen foods	33.0	0.133	0.011	0.084	0.395	0.035	0.084
Canned foods	21.1	0.208	0.053	0.411	0.463	0.096	0.510

Others	28.2	0.330	0.330	0.330	0.330	0.330	0.330

[a] These estimates are very close to zero because of a very large (but insignificant) coefficient for the dummy variable of the corresponding product category.

was positive and significant for firms with total sales under $2 million but negative and significant for firms with sales between $100 million and $700 million. Interestingly, however, the variable is insignificant for firms larger than $700 million in sales.

Buyer Adaptation to Consumer (Market) Response

The modeling results reported above describe the linkage between certain manufacturer strategies and supermarket buyer acceptance. However, to better understand the relationship of the buyer as the channel intermediary between the manufacturer and the consumer (or marketplace), additional data were collected from the participating retail firm on the status of the subset of all products accepted from the original set of products presented by vendors. Table 5 reports the status for these 549 products (29%). Out of the 549 accepted products, 31.9% (175 products) or 9.2% of the original sample presented, were still on the retail shelves selling well nearly two years after the initial vendor presentation. Although 69.1% of the products initially accepted by the buying organization were discontinued within the first two years, buyers reported a variety of reasons for this deletion decision. The three categories buyers most often cited were lack of consumer interest (45.3% of all deletions), expiration of manufacturer introductory allowances (12.9%), and the introduction of a superior competing item (11.5%).

Table 5 also shows the profile of attributes present in the set of products initially accepted by the buying committee as compared to the profile of attributes (variables) of the products that had ultimately been "accepted" by consumers (or by the market) after two years.[3] These comparisons show numerous differences between the attributes present in the group of products accepted by the buyer/intermediaries (buyer acceptance) and the group of products ultimately accepted by the marketplace (consumer acceptance).

The last column in table 5 is an index of the approximate efficiency with which the buying committee was able to predict consumer acceptance computed as the ratio of percent of products accepted by the buying committee and the percent of products "accepted" by consumers in the marketplace after two years. Thus, this ratio is an approximate measure of the degree to which the buying committee (in the role of an agent for consumers) and consumers evaluate new products in an equivalent mannner. A score of 1.00 indicates that buyers were able to perfectly anticipate consumer's final judgment with respect to the importance of the selected attribute. An index greater (less) than 1.00 suggests that buyers "overestimated" ("underestimated") the importance of an attribute, at least as determined by the proportion of all the products ultimately accepted by the marketplace that exhibit this attribute. For example, of all products accepted by the buying committee, 21.7% had test market results presented to buyers as a part of vendors' new product presentation; however, 28.0% of the successful products (i.e., still on shelves after two years) were those that had had such test market results originally presented. The resulting index, .78, suggests that buyers underestimated the importance of test market results in determining ultimate marketplace success.

The attributes for which the index is either very large or very small are pictorially shown in figure 2. For example, products given high scores on product uniqueness by buyers do not necessarily gain consumer acceptance to the same degree (the index is 1.24 showing the possible inefficiency of the buying committee to predict consumer acceptance).

Systemwide Efficiency Implications

Although new product introductions have been widely cited as one of the major modes of conduct by grocery manufacturers, new products are likely to be an equally important strategic tool of distributors as well. Yet, little research has probed the conduct of the retail buying teams, gatekeepers to the supermarket shelves, regarding how they decide to accept or reject the growing number of new product offerings. The statistical model developed in this paper estimated the importance of the various components of a manufacturer's new product strategy in determining the acceptance of a new product by an individual supermarket intermediary. With knowledge of manufacturer new product budgets, these results can be used in the calculation of marginal returns associated with various marketing mix factors and optimum levels and al-

[3] A logistic regression model was also developed to examine the ability of the same set of variables used in table 2 to predict the status (consumer acceptance) of the accepted products after two years. This model predicted correctly 73.5% of the time (less than the buyer acceptance model), and there was no overlap between the two sets of significant variables.

Table 5. Profiles of New Products Accepted by Buying Committee Versus Accepted by Consumers (Marketplace), Two Years After Introduction, by Major Attribute

Variable/Attribute	Products Introduced Total	Buying Committee Acceptance	Consumer (Market) Acceptance	Index of Buying Committee Acceptance to Consumer Acceptance
Number of products	1,899	549 (29.0%)	175 (31.9%)	0.91

location of manufacturer expenditures. When the optimal decisions are implemented, systemwide efficiency increases: profits can be higher for channel members and at the same time prices can be lower for consumers.

The lack of significant positive effects of certain terms of trade (e.g., slotting allowance and free cases) and, indeed, the significant negative effect of others (e.g., bill back provisions) have several implications for total food system efficiency. Although this result appears contrary t certain of the conduct-model's prior expecta tions and contrary to much popular industry per ception (see, for example, *Supermarket New* and *New York Times*), a possible hypothesis i that the presence of certain nonprice incentives like slotting allowances, may be correlated wit inferior products. That is, suppliers may offe additional support for products they fear are no truly unique and, similarly, buyers may indee

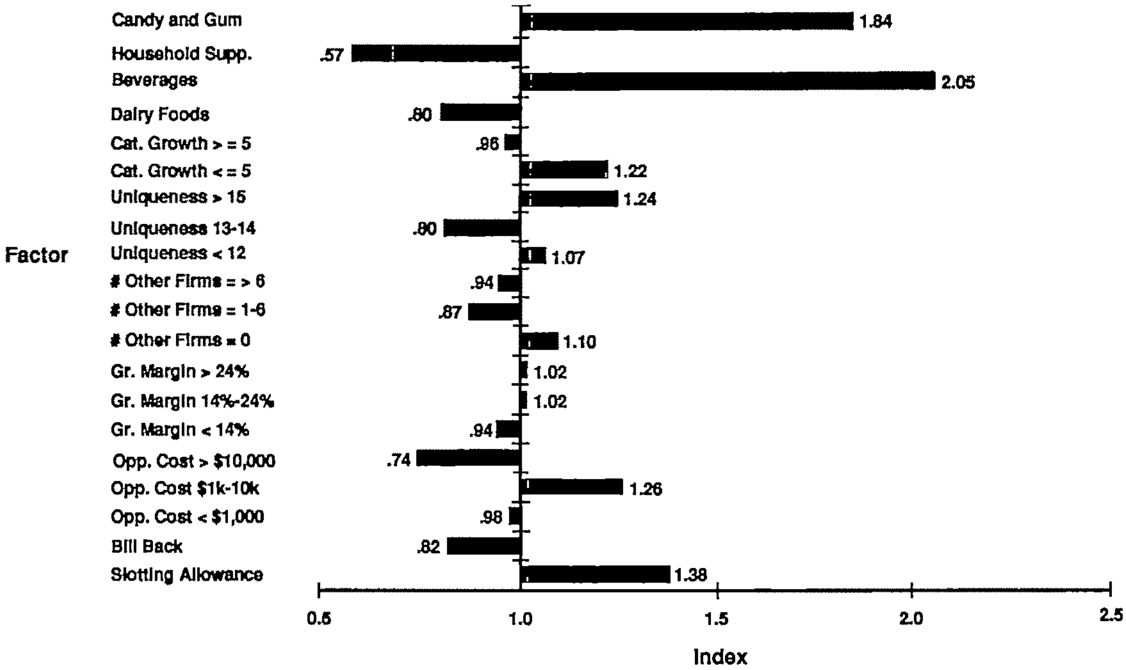

Figure 2. Index of relative factor importance, buyer vs. consumer

recognize and accept truly superior products on their own merits without requiring additional inducements. In fact, when the buyers in the participating retail firm were confronted with this initially puzzling result, they corroborated that the hypothesis accurately described typical industry practice. Moreover, the attribute profile of products that had withstood the test of the marketplace—those selling well after two years—suggests that buyers apparently "overestimated" the importance of the slotting allowances (index = 1.38). This finding also suggests that buyers may initially accept products that are accompanied by slotting allowances, perhaps because of the financial incentive alone, only to discontinue them relatively sooner than competing new items without allowances.

Thus, the implication is that much of the large and currently expanding manufacturer promotional allowances directed to the retail trade may be inefficient if not redundant. This study indicates that manufacturers may be better off by reallocating some of their new product budgets into activities more likely to influence positively both buyers and consumers. However, this is not an easy prescription because, as this analysis has shown, several of the strategy variables that are most influential to buyers (e.g., product uniqueness and category growth) are apparently not weighted as heavily by consumers. That is, retail buyers base new product decisions, at least in part, on a different set of criteria than consumers. Better prediction by retail buyers of ultimate product preference by their consumers is likely to increase both firm (and system) efficiency.

Data collection efforts in this research were somewhat disappointing because various pieces of information were missing (e.g., number of coupons, dollar amounts of advertising, etc.) for a number of items. This is not just a researcher problem; it is also a problem for channel intermediaries in their actual decision-making environments. It appears likely that information from vendors could be much improved by including, and perhaps even standardizing, advertising and promotional materials, the format for discounting schedules, etc., in new product packets. Although some vendors may not initially embrace such a proposal because they fear loss of competitive advantage, overall results would eliminate duplication and waste, thus increasing the efficiency of the entire system.

Finally, our data show that a higher percentage of products were accepted when market research results were presented (39% of products with test marketing or marketing research results were accepted versus 28% acceptance rate for products without these results). As a result, one could hypothesize that, given the high mar-

keting costs of test marketing a new item with consumers, manufacturers instead simply introduce the item to the buyer first. The buyer frequently is in a better position to assess potential consumer demand than a manufacturer. Thus, this procedure may serve as a quick and inexpensive market test. In this sense, recent large numbers of new product introductions may not represent inefficient product proliferation but an efficient manufacturer strategy to increase variety (and profit) while reducing systemwide costs.

Future Research Directions

We are encouraged, based on this research experience with one company, that a richer complement of conduct or strategic variables can be incorporated into economic analysis to improve systemwide efficiency and performance. Further investigation is warranted into the idea that buyers and consumers may use different sets of variables in evaluating new products.

While the empirical approach utilized in this paper has enabled us to describe the judgmental processes of a retail buyer, arguments can be made that we seek a theoretical foundation for the estimated model. The development of a model based on microeconomic theory in which an intermediary's decision to add a new product as one of maximizing the utility of the retail firm could be a worthwhile pursuit. Such a model may include such theoretical constructs as product quality, organizational innovativeness, and competitive advantage, which can directly lead to specification of variables to be included in an analytical model for estimation.

One obvious direction of future research is to replicate this research to additional firms to probe such questions as: Why do certain firms choose particular organizational forms to evaluate new products? What is the impact of these other forms (e.g., no committee) on the acceptance rates? Are some forms more (less) efficient or more (less) beneficial for producers or consumers? Which organizational forms enhance the success of manufacturer strategies? It might be shown, for example, that a reorganization of a distributor's buying process could result in lowering a firm's transaction costs and a probable improvement in system welfare.

An ideal next step in this research stream is to develop a societal balance sheet of costs and benefits coming from the new product introduction activity in the food system. Various measurement questions arise in this endeavor. From the manufacturer's perspective, not only are assessments of costs of R&D and marketing effort needed but so are the opportunity costs of false introductions and early dismissal of likely successes. Further, the importance of new products for the viability of the firms should be measured in monetary terms. Similar costs and benefits can be identified at the intermediary level. While one can debate the existence of any consumer benefits at all from new product proliferation, ample research opportunities are available to increase the efficiency of the process.

Simulation Modeling to Set Priorities for Research on Oyster Production

Darrell J. Bosch and Leonard A. Shabman

Private oyster production in Virginia has declined significantly because of factors including losses from MSX (*Haplosporidium nelsoni*). Increased state and federal funding is being proposed to support research to stimulate oyster productivity. A model of oyster production under uncertainty, including growth, disease, and economic components, is used to aid in setting research priorities. The model shows effects of different types of research information on returns to a representative oyster planting enterprise. Seed harvest technology and accurate knowledge of the salinity threshold at which MSX mortalities occur are found to have greatest promise for increasing profitability of oyster production.

Key words: bioeconomic model, economic returns, MSX, oyster planting, research priorities, seed costs, uncertainty.

Encouraging increased oyster planting on privately leased shellfish beds is a priority of the Commonwealth of Virginia, which is seeking to reverse a long-term decline in private oyster production from 3.65 million bushels in 1956 to 0.58 million bushels in 1986 [Virginia Marine Resources Commission (VMRC) 1979 and 1988]. The factors that are asserted to be primarily responsible for the decline are the disease *Haplosporidium nelsoni* (MSX), which first appeared in the area in 1959 and the continuing inability to develop planting strategies to avoid disease losses (Haven, Hargis, and Kendall; VMRC 1986). The state has proposed increased funding for oyster production research (VMRC 1986). At the federal level, a 1988 bill proposed $68 million to fund ten years of oyster production research (U.S. Congress, House). The result for 1989 is a federal appropriation of $500,000 (U.S. Congress). The strategic decision to increase funding for oyster production research must now be followed by setting of priorities for areas of study within an overall research budget. The objective of this study is to evaluate economic returns to alternative types of oyster production research. A bioeconomic simulation model of oyster production is used to evaluate the effects of alternative types of research information on the returns from oyster production. Model results are used to recommend research priorities to increase productivity in the oyster industry.

Background on Oyster Production

Planting of oysters is an aquacultural enterprise in which immature oysters, called seed, are planted on the bottom of saline rivers and bays and allowed to mature to market size. The time to maturity is correlated with the salinity of the overlying waters. Up to a point, salinity is positively related to the growth rate of the seed because it is associated with a wide range of favorable growing conditions (Kennedy and Breisch). Growth rates approach zero at salinity levels below five parts per thousand (ppt), with maximum growth rates at salinity levels above twelve to thirteen ppt (Loosanoff, Chanley).

Although growth rates increase in a predictable way with higher salinity, higher salinities also increase the potential for significant mortalities from MSX disease (Haven, Hargis, and Kendall). Disease behavior is also seasonal as initial infection can occur during May through

Darrell J. Bosch and Leonard A. Shabman are an assistant professor and a professor, respectively, Department of Agricultural Economics, Virginia Polytechnic Institute and State University.

The authors express appreciation to the Virginia Graduate Marine Science Consortium for providing financial support for this research and to George Norton and Francis Schuler for helpful comments on an earlier version of this paper.

Paper is staff paper number SP-89-25, Department of Agricultural Economics, Virginia Polytechnic Institute and State University.

October and only if salinities in those months are at a trigger level. After an incubation period and in the presence of threshold salinities higher than the trigger salinities, mortality will occur until the onset of colder water temperatures of winter (Andrews). MSX infection reduces oyster yields and lowers oyster condition indices (Haven, Hargis, and Kendall). However, MSX infection poses no danger to humans, and infected oysters can be marketed.

Despite the general understanding of MSX behavior and its relationship to salinity, important specific relationships have not been precisely identified. First, the salinity level that triggers infection is not known with certainty but is expected to range between fifteen and twenty-five ppt (Andrews). Second, the incubation period from infection to mortality is not known. Third, the threshold salinity that induces mortality is equal to or greater than that which results in infection and probably varies between fifteen and twenty-five ppt (Andrews), but the precise threshold is not known with certainty.

Oyster planters choose a grounds location for seed planting in recognition of the trade-off between salinity-associated growth and disease potential. To illustrate, seed costs of up to $4,000 per acre might be incurred to plant 1,000 bushels of seed. Once the oysters are planted, favorable salinity patterns may result in a 1,000 bushel market oyster harvest (a 1 : 1 seed-harvest ratio) with a market value of $12,000. Harvest would occur over a short period at some point two to four years after planting. However, if salinity rises enough to result in disease outbreaks, the initial $4,000 might be lost; conversely, unfavorably low salinities might delay the date of harvest. Clearly, the returns from oyster planting are risky and greatly affected by the choice of planting location. However, grounds availability is not a production constraint because much of the private oyster grounds in the state are currently barren (VMRC 1986).

Oyster researchers have called for studies to improve the understanding of the relationships between salinity and MSX and for the development of techniques for faster disease diagnosis (Ford, Perkins). Such research might permit planters to select grounds with expected salinity high enough to maximize growth rates but without the risk of MSX loss. If disease does occur, faster disease diagnosis might help to save most of the crop.

Even perfect information about the correlation between MSX disease and salinity would not remove planting risk because salinity cannot be known at planting time. Rather, the salinity pattern depends upon streamflows, which in turn depend upon unpredictable weather patterns. The only way to fully remove disease risk would be to plant a disease-resistant oyster (Ford, Perkins).

In addition to MSX disease, economic factors also explain the decline of private oyster production. Specifically, the real price of seed oysters has increased far more rapidly than market oyster prices (JLARC, Shabman and Thunberg). From 1964 to 1987, market oyster prices approximately doubled, while nominal seed prices increased from $1.34 per bushel to $3.06 per bushel. Interviews with private planters indicate that the number of seed per bushel has significantly declined over the period, meaning that real seed costs have increased even more. Thus, another research area might be ways to produce seed at lower cost.

Simulating the Contribution of Research Information to Oyster Planting

A simulation model was developed to evaluate how different types of research information might improve the risk efficiency (reduce the variance and/or increase the expected returns) of private oyster planting and thereby increase private planting. The effect of research information on the risk efficiency of planting was simulated by varying the most uncertain model parameters and determining improvements in risk efficiency of planting with better information. The model was applied to the Rappahannock River in Virginia, the primary private oyster production area in the state.

A representative oyster planter is expected to seek a favorable distribution of net present values (*NPV*'s) of returns from oyster production at some specific river location. The *NPV* from a single crop with a given salinity pattern over the growing cycle is calculated as shown in equation (1).

$$(1)\quad NPV = Y(P - HC)/(1 + r)^n - (SC + T + SP)(SD),$$

where Y is the number of bushels harvested from the enterprise, P is the per-bushel harvest price, HC is the per-bushel harvest cost including delivery to the market location, r is the real monthly before-tax discount rate, and n is the number of

months from planting to harvest;[1] SC is the per-bushel seed purchase price, T is the tax levied by VMRC on each bushel of seed purchased, SP is the seed planting cost, and SD is the number of bushels of seed planted;[2] Y, which depends on disease losses, and n, which depends on growth rates, are salinity dependent. The planter is assumed to be a price taker (Shabman and Thunberg, JLARC). Parameter values used to estimate net returns are shown in table 1.

The oyster enterprise model is summarized in figure 1.[3] Initially, a planting location, year, and month are selected. Planting cannot occur in July, August, or September because of unavailability of seed. After planting, monthly salinity is established based on location and lagged streamflow. The relationship between streamflow, location, and salinity was estimated using salinity measurements collected at various locations in the Rappahannock River from 1970 to 1983 (Virginia Institute of Marine Science) and daily streamflow measurements available through the Hydrologic Information Storage and Retrieval System (HISARS) administered by the Virginia Water Resources Research Center. The estimated model based on 535 observations is the following (t-statistics are in parentheses):

$$(2)\quad \begin{aligned} S = {} & \underset{(96.78)}{19.588} - \underset{(-55.60)}{0.00251658K^2} - \underset{(-3.63)}{0.209454SF1} + \underset{(5.73)}{0.0000002SF1^2} - \underset{(-7.79)}{0.1732264SF2} \\ & - \underset{(-6.08)}{0.1328310SF3} + \underset{(2.15)}{0.0119554KT} \quad R^2 = .87, \end{aligned}$$

where S is estimated salinity in ppt; K is kilometers (km) from the river mouth; $SF1$, $SF2$, and $SF3$ are the sums of daily streamflow readings (in 10,000s of cubic feet per second) for 0 to 30, 31 to 60, and 61 to 90 days, respectively, preceding the salinity measurement; and T is a dummy variable that takes a value of 1 for high tide and 0 for low tide. The coefficients have the expected sign with salinity decreasing as streamflow and distance from the river mouth increase.

Oyster growth is related to season, salinity, and size as shown in the following equation, which is based in part on studies by Askew (1972, 1975, 1978):

$$(3)\qquad W_t = W_0 e^{a_t b_j c_k},$$

where W_t is the oyster's weight at the end of month t, W_0 is the weight at the beginning of month t, e is the base of natural logarithms, and a_t represents the seasonal parameter. The fastest growth rates are realized in late spring and early summer and the slowest growth rates occur in winter. The a_t values were calibrated using data from Virginia oyster growth studies (Andrews, unpublished data, Virginia Institute of Marine Science).

The parameter b_j was included to represent salinity effects because of the recognized relationship between grounds production potential and salinity (Haven, Hargis, and Kendall; Kennedy and Breisch). These parameter values were derived with the help of scientists at the Virginia Institute of Marine Science (VIMS) and oyster producers. They were asked about the length of time required to produce a three-inch oyster from a one-inch seed in the Rappahannock River on grounds of varying salinity. They indicated that two years are required for salinity levels greater than thirteen parts per thousand (ppt), three years for salinity levels between ten and thirteen ppt, and four years for salinity levels between six and ten ppt. No growth occurs for salinity levels less than six ppt. Values of b_j that would cause these growth rates to be achieved were solved for iteratively.

The instantaneous annual growth rate that depends on the oyster's weight k at the beginning of the season is represented by c_k. The growth rate declines as oyster size increases. The values for c_k were based upon relationships derived by McHugh and Andrews for Chesapeake Bay oysters.

Oyster mortality is also calculated each month. Two sources of mortality considered are salinity-independent background factors, which include losses to predation and smothering by silt,

[1] Harvest cost is constant at $4.54 per bushel, based on estimates obtained in planter interviews in the Rappahannock River area in April 1988. Planters noted that costs, particularly for hand tong harvest, increase when oysters are less dense on the bottoms. However, with lower density, planters are more likely to use a mechanical dredge for harvest, which lowers costs compared with hand tong harvest.

[2] Most private grounds in the river are currently barren. Consequently, the planter, whose expectations as to salinity level at a given location change, is more likely to vary locations than to vary the amount of seed planted at a given location.

[3] Average costs are not affected by location; therefore, optimal enterprise size need not vary by planting location and a constant enterprise size of 1,000 bushels is evaluated for all planting locations.

Table 1. Economic and Physical Production Parameters Used in Oyster Enterprise Model

Parameter	Value	Parameter[a]	Value
			($/bu.)
Seed count/bu.[b]	600	Jan. price	10.21
Seed size (in.)	1.5	Feb. price	11.67
Seed price ($/bu.)[c]	3.06	Mar. price	11.81
Seed tax ($/bu.)	0.15	Apr. price	12.57
Planting cost ($/bu.)	2.08	May price	13.75
Transplanting cost ($/bu.)[d]	5.84	June price	11.30
Harvest cost ($/bu.)	4.54	Jul. price	13.33
Monthly interest (%)[e]	0.80	Aug. price	13.11
		Sep. price	12.04
		Oct. price	13.55
		Nov. price	12.63
		Dec. price	13.93

[a] Monthly average harvest price equals weighted seasonal average price for Rappahannock River oysters for 1984–87 plus or minus a monthly adjustment based on the average deviation of each monthly price from the seasonal average price for 1981–87.
[b] Seed count and size estimates were obtained from planter interviews.
[c] Seed prices are a weighted average of prices for public grounds seed for 1984–87 (VMRC 1988).
[d] Transplant charges include harvesting the premature oysters, transporting them upriver, and planting them on the new site.
[e] The interest rate is a real risk-adjusted rate. The average one-year Treasury Bill rate (Board of Governors of the Federal Reserve System) for 1984–87 was used as the risk-free nominal interest rate. The inflation rate represented by the average annual change in the implicit price deflator for gross national product (U.S. Department of Commerce) for 1984–87 was subtracted and a 5% risk premium added to account for risk.

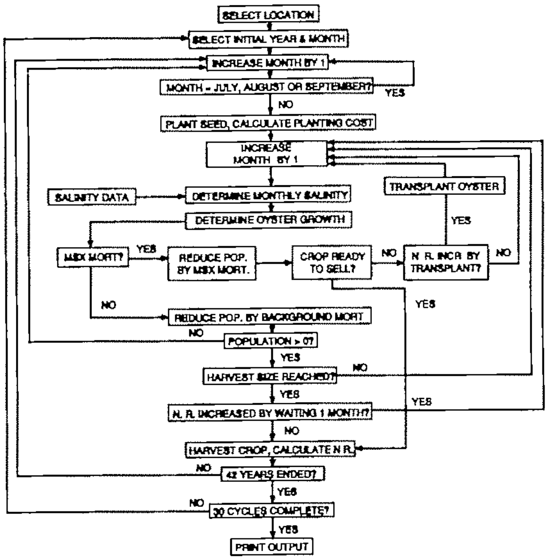

Figure 1. Oyster bioeconomic model

and the salinity-dependent disease MSX. The inverse relationship between mortality and oyster size derived by Askew (1975) was used to calculate background mortality.

A model of infection and mortality from MSX was constructed based on research summarized in Andrews as well as interviews with scientists at VIMS. Within the model, infection occurs only during May through October and when salinities are high enough to trigger infection. After MSX infection, a period of incubation is required before mortalities begin. Mortalities occur only from June through September and when salinities exceed a mortality threshold that is possibly higher than the level that triggers infection. Monthly mortalities average 20% of the month's beginning population. If MSX mortalities occur during the June–September period, surviving oysters are eliminated in the following June–September period assuming that salinities continue to equal or exceed the mortality threshold.

No growth occurs when the oyster has been infected and salinities are above the mortality threshold. If salinity falls below the mortality threshold but remains above ten ppt, no MSX-related mortality occurs and normal growth resumes. However, the oyster remains infected and mortalities resume when salinity rises above the mortality threshold. If salinity falls below ten ppt, the oyster eliminates all MSX infection (Sprague, Dunnington, and Drobeck).

Calculation of MSX mortality is a critical feature of the model. However, the exact salinities that trigger the infection and subsequent mortality from MSX are uncertain. The specific uncertainties are discussed in detail below.

If MSX mortality is observed and oysters have reached harvest size, oysters are harvested. If oysters are not market size, the possibility of transplanting oysters to lower salinity grounds is considered. Transplanting requires picking up the oysters using hand tongs or dredge, moving them by boat to an upriver location, and distributing them on the bottom. Whether transplanting is economical depends on the number of months that salinities remain high enough at the site to sustain MSX mortality. Oysters at a given location are transplanted only if doing so increases expected net returns for the entire distribution of salinities evaluated.

After oysters have reached market size of three inches, the planter may wish to wait another month before harvesting in order to obtain a higher price. Oysters are harvested only if net returns from harvesting in the present month exceed the discounted returns from waiting one month, recognizing the background mortality loss from waiting.

After the original crop has been harvested or destroyed by MSX, new seed are planted at the original site and the simulation continues for a forty-two-year period in order to capture a full historical pattern of salinities. A distribution of *NPV*'s for a given location is generated by repeating the entire forty-two-year cycle thirty times. By repeating the runs at multiple sites along the river, the model was used to calculate the distribution of *NPV*'s at grounds locations with different salinity patterns.

Multiple streamflow sequences, needed to predict monthly salinities, were synthetically generated using procedures suggested by Fiering and Jackson. The logarithm of streamflow in year i and month j ($LSF_{i,j}$) was generated as follows:

$$(4)\quad LSF_{i,j} = \overline{LSF}_j + (r_j s_j / s_{j-1})\, DEV_{i,j-1} + t_{i,j} s_j (1 - r_j^2)^{0.5},$$

where $\overline{LSF}_j$ and s_j are the mean and standard deviation of the logarithms of flow for month j; r_j is the correlation between the logarithms of flow for month j and month $j - 1$;[4] t is a random normal deviate with mean 0 and variance 1; and $DEV_{i,j-1}$ is the deviation between $LSF_{i,j-1}$ and $\overline{LSF}_{j-1}$. Means, standard deviations, and correlations of monthly flows were calculated from actual Rappahannock River data for 1910–86. Flow logarithms were converted to streamflows and used to predict salinity.

The simulation model was used to determine the potential contribution of different types of research information to the risk efficiency of oyster planting in the Rappahannock River. If the simulation results show that improved information would not alter the efficiency of planting, then research in these areas will have limited benefits and should not be pursued. However, choosing among the research areas that appear to have value will require information from outside the simulation model and is discussed later.

Model Validation

The structure of the simulation model was developed based on an intensive review of the biological literature and a series of extended interviews with professional oyster biologists at the Virginia Institute of Marine Science and private oyster planters. Key parameters from the growth and disease submodels were quantified using experimental data and expert interviews. These steps were taken to increase the model's face validity to oyster production experts (Law and Kelton).

Model results to be discussed later (table 3), show that for all but the nineteen-ppt mortality threshold, expected returns were negative at the mouth of the river and increased for locations further upriver where salinity levels and chances of MSX infection were lower. These results are consistent with the trend for planters to abandon high-salinity planting locations in the main portions of the Chesapeake Bay in favor of lower-salinity upriver locations after the onset of MSX in 1959 (Haven, Hargis, and Kendall). More detailed validation of model results is hampered by lack of complete data on the relationship between planting location, oyster growth, and oyster disease. Indeed, increased funding for oyster production and disease research is being emphasized because of data limitations and uncertainty about key model relationships.

Research Area 1: Faster Diagnosis of MSX

Planters perceive a trade-off between achievement of higher growth rates in higher salinity waters and the greater chance of losses to MSX disease in these waters. The risk involved in making this trade-off might be more manageable if faster diagnosis of the disease were possible. The planter then could plant in higher salinity waters for faster growth and salvage the crop for market or transplanting if salinities increase sufficiently to trigger the disease. MSX diagnosis currently requires extensive laboratory tests by shellfish pathologists (Dyckman). Research could focus on simpler, faster tests to detect the disease.

The simulation model was used to examine the effects on *NPV*'s of varying the length of time required to diagnose and harvest diseased market oysters from one-half to two months.[5] Table 2 reports the results for several river locations, using a mortality threshold salinity of eighteen ppt. Further discussion follows below on the mortality threshold; however, the results

[4] Month varies from 1 to 12; therefore, when j equals 1 (Jan.), $j - 1$ equals 12 (Dec.).

[5] Better methods of diagnosis might also be developed to determine if seed are infected by MSX. However, MSX infection is transmitted by an undetermined host, and infection and mortality are primarily determined by salinity at the grounds rather than presence of infection within the seed.

Table 2. Effects of Varying the Time Required to Harvest MSX-Infected Oysters on Net Present Values of Returns per 1,000 Bushels of Oysters

Note: Returns are stated as NPV's for a 42-year production cycle assuming that 1,000 bushels of seed are planted initially and each time oysters are harvested or lost to disease.

[a] Distances are kilometers from the mouth of the Rappahannock River.

reported in table 2 were insensitive to varying the threshold between fifteen and nineteen ppt. Mean net returns were increased in locations close to the river mouth where faster diagnosis permitted diseased oysters to be transplanted sooner. Mean returns increased little in upriver locations where transplanting was not economical. The most important result is that the maximum expected *NPV* occurred at the 30.0 km location, where no losses to MSX occurred. The variance at this location also was reduced compared with that at 25 km. Thus, no matter how fast the diagnosis, the economically prudent location was at 30 km, where MSX was avoided altogether. Increasing the risk of MSX disease loss in order to achieve higher growth rates was not an economically sound strategy. This simulation makes clear that planters would be best served by information telling them how to avoid MSX, which requires understanding of the relationship of the disease to salinity, or by development of an MSX-resistant seed.

Research Area 2: Relating Salinity to MSX Mortality

Management of oyster planting in the presence of MSX is made difficult by three sources of uncertainty: (*a*) the salinity that triggers MSX infection in the oyster; (*b*) the number of months required for MSX infection to incubate in the oyster before mortalities begin; and (*c*) the mortality threshold, that is, the salinity level at which oyster mortalities occur from MSX. Research trials in various sections of the river could be designed to monitor salinities and disease responses. The results could be used to determine which planting locations are most desirable from a risk-returns standpoint.

To simulate the value of improved information on these three factors, appropriate parameters within the disease loss component of the simulation model were varied for each of the simulation runs at each river location. First, the number of months of MSX incubation required before mortality occurs were varied with the infection trigger held constant at fifteen ppt and the mortality threshold set at eighteen ppt. Increasing the incubation period from one to three months caused relatively small increases in expected net returns in the downstream areas where salinities rose above the mortality threshold. For example, at 20 km the expected *NPV* was \$4,808 for a three-month incubation compared with \$3,781 for a one-month incubation. However, in upriver areas where salinity remained below the mortality threshold, the length of incubation had no effect on returns. Also, expected returns were still maximized by planting in these areas rather than further downstream.

Second, the salinity that triggers MSX infection was varied with the mortality threshold held constant at eighteen ppt and the incubation period set at two months. Increasing the salinity trigger had little effect on the location where expected returns were maximized. Increasing the trigger caused increases in returns in downstream areas where salinities were above the mortality threshold but did not affect returns in areas where salinities remained below the mortality threshold.

Third, the salinity threshold that induces mortality in infected oysters was varied between the values of fifteen and nineteen ppt. As noted, the threshold salinity may occur over a range from fifteen to twenty-five ppt (Andrews); however, the upper bound of nineteen ppt was chosen because salinity levels in the river seldom exceed twenty ppt at any location. For these simulations the trigger salinity for infection was held

Table 3. Effects of Variations in the Threshold Salinity for MSX Mortality on the Net Present Value of Oyster Enterprise Returns

Note: Net present values refer to an enterprise in which 1,000 bushels of seed are planted initially and each time oysters are harvested.
[a] Distances are kilometers from the mouth of the Rappahannock River.

constant at fifteen ppt and the required incubation period was maintained at two months. Table 3 shows that for each threshold salinity, the mean *NPV* increased with distance from the river mouth until a maximum was reached; moving further from the river mouth reduced salinity levels and reduced the chances of MSX infection. After net returns reached a maximum, further movements upriver reduced returns because lower salinity caused oysters to grow more slowly, increased interest costs for the seed investment, and reduced yield by increasing total background mortality.

As the threshold salinity for MSX mortality was increased from fifteen to nineteen ppt, the maximum expected *NPV* increased substantially and occurred closer to the river mouth. With a fifteen-ppt salinity threshold, the risk-efficient distance was 45 km, with an expected *NPV* of $7,532 and a standard deviation of $687. With a nineteen-ppt salinity threshold, the risk-efficient location was 20 km with an expected *NPV* of $13,512 and a standard deviation of $513. Thus, if research found that the salinity threshold was nineteen ppt, planters could choose a location where expected returns are two to three times higher compared with upriver locations with variance essentially unchanged. However, research may find that the threshold is as low as fifteen ppt. The implications of this possibility for research priority setting are considered below. In any case, the simulations clearly indicate that only the salinity threshold for mortality is an important determinant of economic return.

Research Area 3: Development of MSX-Resistant Seed

Research toward development of an MSX-resistant oyster has been underway for a number of years. In order to develop MSX-resistant seed, the host that spreads the MSX virus must be identified in order to replicate the disease in the laboratory. Then breeding or immunization strategies to induce resistance can be evaluated (Schmidt).

The last column in table 3 reports the returns from planting MSX-resistant seed. These results were simulated by setting the MSX mortality threshold at a higher salinity level than was ever observed in the river. While MSX resistance will permit positive returns to be earned at all locations in the river, the number of locations where

MSX resistance increases the mean and reduces the variability of *NPV*'s diminishes with higher threshold mortalities. For example, at nineteen ppt the payoff for MSX resistance in terms of increased expected *NPV* is $256 ($13,768 − $13,512). However, if the threshold salinity is fifteen ppt, the payoff to MSX resistance increases to $6,236 ($13,768 − $7,532). The implications of the interdependence between the threshold salinity for mortality and the payoff from MSX resistance are considered below.

Research Area 4: Lower Seed Costs

Research that lowers the per unit cost of oyster seed is an alternative to spending funds on disease research. Using a mechanical or suction dredge to harvest seed rather than the labor-intensive, hand-tonging method could lower seed costs by 80% (Shabman and Thunberg). However, the state's oyster management plan (VMRC 1986) repeats a long-held concern that dredging might result in damage to certain types of seed beds. Because mechanical oyster seed harvest occurs in many other areas, such as the Potomac River and in Maryland, the extent of this damage and the cost effectiveness of repairing it by shelling grounds after harvest could be evaluated by research.

Another possibility would be development of low-cost hatchery technology (Kennedy and Breisch). Seed hatchery technology for the bay area has been under development for a number of years in both Maryland and Virginia. Recent prices for hatchery seed have averaged $3.50 per 1,000 seed (Webster and Meritt), while costs of James River seed have averaged over $5.00 per 1,000 seed. However, hatchery seed is not yet economically viable because of its smaller size and lower survival rate.

The effects of research that lowers seed costs are evaluated by determining the reduction in seed costs required to match the increase in net returns resulting from the availability of an MSX-resistant seed. The model was rerun to determine the seed price reduction needed to make the expected *NPV* without resistance equal to $13,768, the expected *NPV* obtained with MSX resistance at the river mouth. As discussed previously, the return to MSX resistance depends on the salinity threshold that causes MSX mortality; therefore, the necessary seed price reduction also varies by mortality threshold. The necessary reductions by threshold are: fifteen ppt, $1.12 per bushel; sixteen ppt, $0.66 per bushel; seventeen ppt, $0.33 per bushel; eighteen ppt, $0.18 per bushel; and nineteen ppt, $0.06 per bushel. These reductions vary from 2% to 37% of the $3.06-per-bushel base price. Thus, relatively small percentage reductions in seed price are likely to match the benefits to planters from an MSX-resistant seed.[6] These percentage reductions would be affected by changes in the ratio of market prices to seed prices. A decline in market prices relative to seed prices would lower the required reductions and make seed research more advantageous relative to development of MSX-resistant seed.

Setting Research Priorities

The simulation results eliminated some potential research priorities, including faster diagnosis of the disease, better knowledge of the salinity that triggers infection, and better knowledge of the time required for infection to incubate in the oyster before mortality. The simulation results support further consideration of seed harvest technology, seed hatchery technology, MSX-resistant seed, and the salinity threshold that causes MSX mortality. In order to set priorities among these possibilities, factors outside the simulation model must be considered.

Following Atkinson and Bobis, assuming the research funds administrator is risk neutral, the ranking can be based on the ratio of the expected present value of benefits and costs (B/C). The expected benefits of research depend on the joint probability that (*a*) the research will be successful, and (*b*) its results applied. Expected research benefits are calculated by multiplying this joint probability times the increase in the economic returns from the production process being studied if the research is successful and its results are applied. Research costs are the budget expenditures necessary to pursue research (Atkinson and Bobis). Simulation of the production process illustrates the economic benefits of research information if the research achieves its objectives, is adopted by producers, and is applied in a timely fashion. Clearly, the research administrator's expectations for the present value of benefits will depend not only upon the simulation results but also upon his subjective estimate of the probability for timely

[6] The possibility that increasing or decreasing the interest rate might significantly increase the advantage of MSX-resistant seed was evaluated. However, the required reductions in seed price needed to match the benefits from MSX resistance were insensitive to variations in the interest rate.

success and adoption of the research. The research administrator must also form a subjective estimate of research costs. Thus, the B/C is affected by four additional aspects of oyster research not addressed by the simulation model: the probability of research success, the probability and rate of adoption, the timing of benefits, and annual research expenditures.

Seed Harvest Technology Research

The research objective is development of mechanical seed harvest techniques (in lieu of hand-tong harvest) that lower per unit seed production costs without harming the long-term productivity of the public seed-growing areas, particularly in the James River. Evaluation of alternative mechanical harvest techniques combined with shelling to repair any damage done to the seed-growing bottoms could reduce seed costs in two ways. First, mechanical harvest would lower the cost per bushel of seed harvest. Second, replacing clean shell on harvested beds would promote more abundant setting of seed oysters on the beds. Because these techniques are used in Maryland, in the Potomac River, and on private seed grounds, the probability of research success for this project is high and the total cost will be low.

The probability of adoption of the new technology is more problematic. Historically, seed harvesters who use traditional hand-tong technology have resisted mechanical harvesting. However, given the declining number of hand tongers, this resistance should erode over time (Santopietro). On balance, this research area should have the highest B/C ratio due, in particular, to the high simulated benefits, the high probability of immediate success, the prospects for adoption, and the low cost.

MSX Threshold Research

The research objective would be to determine the threshold salinity that results in MSX mortality. The research would require an experiment that plants seed oysters at several locations over a period of years, monitors salinity, MSX disease incidence, and mortality, and then analyzes the data to isolate the relationships of interest. Although salinity is stochastic, table 3 makes clear that knowledge of the MSX mortality threshold would affect the choice of planting location. The benefits from successful research on this topic are uncertain and depend upon the research results. If the mortality threshold is low, then the realized payoff from this research would be low, although such results would provide justification for continuing the development of MSX-resistant seed. If the threshold is high, the payoff from this research will be high. The expected costs for such research to support the scientific personnel and equipment required for monitoring several locations for an extended time would be high. However, the probability of success would be high since the research procedure is a standard experimental design to better quantify a relationship about which much is already known.

If the salinity relationship is more precisely quantified, adoption of the information for planting decisions will require education of the planters about the results of the research. The B/C ratio for this project likely would be lower than for seed harvest technology research because of its higher cost and the uncertainty about the benefits. However, the B/C ratio likely would be higher than for hatchery technology and MSX research (discussed below) because of a high probability for research success.

Seed Hatchery Research

The objective of seed hatchery research is to provide seed at lower cost and with equal or better survival and growth potential than is currently available from natural seed-growing areas. Hatchery technology offers the potential to use breeding techniques to control seed size, shape, disease resistance, and other growth characteristics to produce a qualitatively better seed than is available from public bottoms (Austin, Dupuy, and Haven). Hatchery feasibility research has been conducted in the Chesapeake Bay area for several years (Greer), and as yet hatchery seed is not cost competitive with seed produced from public seed grounds even though hatcheries are already used in other areas such as the Pacific Northwest (Kennedy and Breisch). Thus, the probability of near-term success for economical hatchery production is unclear. Furthermore, the nature of the research makes hatchery technology studies more expensive than seed harvest research. In particular, hatchery research would involve genetic and environmental techniques to increase larval survival rates (Kennedy and Breisch), high-cost efforts because of their intensive use of scientific person-

nel and facilities. As a result, the expected cost of hatchery research is likely to be high. The probability of adoption given research success is likely to be high. Overall, the B/C ratio for hatchery research is likely to be lower than for public seed research primarily because of the high cost of hatchery research and lower probability of research success.

MSX Resistance Research

MSX research has the objective of developing an MSX-resistant seed that would ideally be no more costly than nonresistant seed. However, planters might also be willing to pay a higher price for the MSX-resistant seed if the higher prices were more than offset by economic gains from reduced MSX mortalities. The benefits of MSX resistance research depend upon the salinity threshold that induces mortality. If the mortality threshold is high, the benefits from MSX resistance will be low. The probability of immediate research success for this project is low. MSX research has been conducted almost since the disease was first diagnosed in Virginia waters in 1959, and researchers still cannot replicate the disease in the laboratory. Therefore, expected costs of this research are high. Although the probability of successful development is low, if developed the probability of adoption of MSX-resistant seed is high. The B/C ratio for MSX resistance research is probably the lowest of the four project areas primarily because of the low probability of success. However, the B/C ratio would be increased if the salinity threshold were low and only limited grounds were available in areas where this threshold is not exceeded. In that case, MSX resistance could lead to removal of a grounds constraint and increased plantings as well as increasing the returns per acre.

Conclusions

This study employed procedures to determine that research areas with the greatest potential to increase returns to oyster producers are seed harvest technology, the salinity threshold at which MSX mortality begins, seed hatchery technology, and development of MSX-resistant seed. Based on considerations not included in the simulation model, seed harvest technology and the MSX-mortality threshold are considered the most promising of the four research areas for increasing oyster industry profitability. Both of these areas would involve specific research projects applied to the goal of enhancing profitability of private oyster culture. The two least promising areas of research are development of hatchery technology and MSX resistance; they are oriented more toward basic research focused on increasing the scientific understanding of oyster biology and oyster disease. Given the importance placed upon basic research by oyster biologists (Sprague) and research administrators (Perkins), projects such as evaluation of mechanical seed harvest have received little funding support. However, funding such applied projects would not require abandoning basic research. Instead, applied projects should be part of a research portfolio because they are likely to produce valuable benefits for the oyster industry in a relatively short time.

The usefulness of simulation modeling for agricultural research evaluation is acknowledged (Kislev and Rabiner; Goodwin, Sanders, and Hollanda; Norton et al.; Pinstrup-Andersen and Franklin; Ruttan). While simulation models can show economic effects of research information, a comprehensive model requires subjective probability estimates of research costs and the potential for successful completion and adoption of research. Much of the peer reviewing of research proposals considers the probability that the research objectives can be achieved within the requested budget. Nonetheless, the peer review process could be structured to elicit more information on the research's probability of success, probability of adoption, and probability of obtaining different levels of benefits. Simulation models can help determine types of probability information needed to set research priorities.

Optimal Scheduling in Shrimp Mariculture: A Stochastic Growing Inventory Problem

Eithan Hochman, PingSun Leung, Lawrence W. Rowland, and James A. Wyban

Appropriate management tools are required for the successful introduction of advanced intensive technology in shrimp mariculture. This paper presents a stochastic dynamic decision model for evaluating the potential of the round pond technology practiced at the Oceanic Institute in Hawaii. The model provides the optimal stocking and harvesting schedules for a shrimp pond using a set of intra- and interseasonal decision rules. These rules are expressed as cutoff revenues when both prices and weights are considered random and as cutoff prices and cutoff weights when only prices or weights are considered random. The pond is not harvested if the current realized revenue is less than the cutoff revenue. The model simulates optimal scheduling using a set of 1986 shrimp prices for the case of random prices. Net profits are approximately doubled using the optimal schedules compared to conventional fixed scheduling schemes. The model also evaluates the economics of controlled environment.

Key words: decision model, growing inventory, optimal scheduling, shrimp.

Shrimp aquaculture is a potential industry in the Pacific, but is not profitable with current prices and existing technology. New management strategies and technologies are essential for improving the profitability and competitive potential of the Pacific region in the world shrimp market.

Shrimp ranks second in volume, behind tuna, and first in value of total U.S. seafood consumption. The U.S. is the world leader in shrimp consumption, consuming over 600 million pounds annually. Japan is a close second. Tropical, or penaeid, species represent the major part of the shrimp market in the U.S. and Japan. Worldwide shrimp culture represents approximately 15% of the four billion pounds of shrimp placed on world markets. Farm-raised shrimp could constitute about 25% of the world market by 1990 (U.S. Dep. of Commerce), and about 35% of the tropical shrimp market (Aquaculture Digest).

This paper presents a model for efficient management of shrimp farms in the Pacific region with an emphasis on the optimal market age of cultured marine shrimp. This quantitative management tool, which determines the optimal market age in a dynamic uncertain environment, will contribute to a successful shrimp culture industry.

Pacific shrimp farms have the capacity to produce several crops a year, and this is important to maximize profit. Determining the correct time to harvest is a major problem. Higher potential prices for larger shrimp are weighed against selling smaller shrimp and starting a new crop. There are also seasonal variations in shrimp prices and growth rates.

Risk is involved because the decision concerns future activities and the decision process is implemented at specified future time intervals. Two elements of risk are analyzed in this paper: the biological growth process, because of the limited practical experience, and the uncontrollable market price faced by the Pacific pro-

ducers, who are a small part of the world market. This complicates the identification of the optimal market age. Other types of risk such as damaging algae blooms or viral attacks are not considered here. The basic management unit in this analysis is a pond. This implies that risk is considered to be identical across all ponds in a farm.

Conceptual Framework

This section introduces the conceptual framework for determining the optimal harvesting policy for a single pond. This is an important operating problem for tropical and subtropical shrimp farms. The focus of attention is on the continuous operation of a single pond. Thus, the shrimp producer operates within a given capacity and his decision is short-run in nature. Nevertheless, his production and pond management decisions are carried over time. Time enters at two levels: (*a*) the age of the growing crop of shrimp, and (*b*) the calendar date of harvesting.

In this context, the case of cultured shrimp is an extension of the sequential decision model of growing inventory developed and applied to a broiler producing firm (Hochman and Lee, Rausser and Hochman). There is a close resemblance between these two growing crops. At each age the size distribution and quality of the animals are close to homogenous in the sense that variation in the distribution is very small under normal operation. Therefore, for a given age, the grower faces a dichotomous decision: whether to sell the crop and enter the new period with a new crop, or to keep the old crop and defer the sale decision to the next period.

The differences between the two crops require extension of the framework beyond the broiler model. While the broiler growth processes are well known, the shrimp aquaculture technology is in its infancy. Hence, the proportion of factors that are uncontrolled is considerably higher than with broilers. For example, the air and water temperatures, waste products, and other water quality determinants are hard to control and subject to random variation. Another feature which characterizes shrimp production is the positive relationship between the price and the size which implies a significant differentiation of the product. These distinctions are absent in broiler operations. However, for both crops, risk is introduced through uncertain market prices. Thus, in the case of the shrimp operation, risk is introduced both through uncertain weights and uncertain market prices.

The only operational management model for shrimp culture was developed by Karp, Sadeh, and Griffin. They used dynamic programming to determine the optimal stocking and harvest rates of *P. stylirostris* in the Southwest, where production is continuous for only eight months in a year. However, their dynamic program was exceedingly large with 3,501 different states and cumbersome to apply in a practical setting. In addition, their model placed a heavy emphasis on environmental uncertainty, which is great in the southern United States, and assumed prices were fixed. In contrast, the conditions in the tropics allow year-round growing of shrimps. In that case, price uncertainty is as important as environmental uncertainty.

The state of the system in shrimp culture is defined by: (*a*) the age of the crop as it relates to weight (the growth process) and by extension to the price of shrimp through the price/size relationship; and (*b*) the calendar date of the year through the effect of seasonality on the physical growth processes as well as on the shrimp prices. Thus, the gross revenue per animal received from selling a given crop of age x weeks at a calendar week t can be expressed as[1]

$$(1) \qquad R_n(x, t) = W_n(x, t)P_n(x, t)$$

for $x = x_0, x_0 + 1, \ldots, X$ and $t = 1, 2, 3, \ldots,$ 52 weeks, where $W_n(x, t)$ is the current weight and $P_n(x, t)$ is the current price.

The age of the crop determines both the weight (or size) and the price. There is also a seasonality effect (i.e., the chronological date, t, of the year) on revenue through environmental impacts (e.g., temperature) on the growth of the animal and/or through the seasonality of demand (e.g., Christmas time).

It is assumed that, although the shrimp producer knows the current revenue, next week's revenue includes stochastic (random) elements that make its cash value uncertain. Therefore, without loss of generality, revenue is assumed to be a random variable with a known distribution $h(R)$ that may be univariate if either weight or price are random, or bivariate if both price and weight are random. Thus, the value R_n is the current sales revenue from the density $h(R)$.

[1] The present model is formulated on a per animal basis and mortality is introduced explicitly in the profit calculation. Mortality is assumed to be density-independent due to lack of information. However, this can be modified easily when additional information becomes available.

The case of random prices is characterized by a price-taking firm marketing either to local or export markets. A firm marketing most of its product to a stable local market may consider the price-quantity relation as deterministic. Stochastic variations in weight may be caused by fluctuations of temperatures as well as other environmental factors. Also, when new technologies are introduced, randomness in the weight figures should be considered.

The deterministic cost function is defined as $C(x, t)$ which has fixed costs per crop (mainly the post-larva purchase costs) and variable costs which depend on age such as feed, labor, and energy costs. The immediate net return can then be calculated as $R_n(x, t) - C(x, t)$. Thus, the problem of continuous optimal shrimp production and harvesting can be formalized as a Markovian dynamic programming model.

Let f_n represent the maximum expected return for the last n periods (weeks). If the producer begins at stage n with a crop at age x and calendar date, t, then,

(2)

$$f_n(x, t) = \max_{R^*(x,t)} \left\{ \int_0^{\infty} M(R_n(x, t), x, t)h(R)_t dR_t \right\}.$$

The decision rule is to sell the crop or to keep it. Thus, the optimal policy has the form,

$$(3) \qquad M(R_n(x, t), x, t) = \begin{cases} f_{n-1}(x + 1, t + 1), & \text{if } R_n < R^*(x, t) \\ R_n(x, t) - C(x, t) + f_{n-1}(x_0, t + 1) & \text{if } R_n \geq R^*(x, t), \end{cases}$$

for $x = x_0, x_0 + 1, \ldots, X - 1$; $t = 1, 2, \ldots,$ 52 weeks.

The decision is such that for each age, x, and calendar week, t, if the current realized gross revenue, $R_n(x, t)$, is less than $R^*(x, t)$, keep the crop and delay the decision to sell for another week, otherwise sell the crop if $R_n(x, t) \geq R^*(x, t)$. Therefore, $M(R_n(x, t), x, t)$ is a dichotomous return function that can take one of the two values, according to whether the decision is to keep or to sell the crop. By Bellman's principle of optimality, for all values of $R_n(x, t)$ that fall within the domain of the decision to keep, $M(R_n(x, t), x, t)$ will take the value of maximum expected returns for the last $(n - 1)$ periods, i.e., $f_{n-1}(x + 1, t + 1)$ and for the decision within the domain of the decision to sell, $M(R_n(x, t), x, t)$ will consist of the realized immediate net returns, i.e., $R_n(x, t) - C(x, t)$ plus the maximum expected returns, in the case of a decision to sell, for the last $(n - 1)$ periods, i.e., $f_{n-1}(x_0, t + 1)$.

The optimal policies that result consist of fifty-two vectors of cutoff revenues, $R^*(x, t)$. Each one of the vectors represents the solution for a given week, t, in the year. The fifty-two cutoff vectors depict the impact of the calendar time, while any given vector of cutoff revenues is related to the age of the growing inventory, i.e., for each age a critical value of revenue is defined such that any current realized revenue that is below it will result in a decision to keep the crop and wait for next week, otherwise the decision is to sell the crop.

The Homogenous (Calendar Independent) Case

In the absence of seasonality, if both the environmental and biotechnological conditions that affect the weight distribution of the animal and the market conditions that determine the price distribution are the same and identical in each and every calendar week, the vectors of cutoff revenues will be identical for each of the fifty-two weeks of the year. In this case the calendar week, t, is omitted from equation (1) to yield,

$$(4) \qquad R_n(x) = W_n(x)P_n(x)$$

for $x = x_0, x_0 + 1, \ldots, X$, where $W_n(x)$ and $P_n(x)$ are the corresponding current weight and price.

Note that the calendar date, t, is not in the equation because it will not affect the current value in the homogenous case. Also, the revenue distribution, $h(R)$ will remain the same for all weeks of the year.

In this case the dichotomous decision can be depicted by the following set of optimal decision rules for each corresponding age group:

$$(5) \quad V(x) = \max\left\{R(x) - C(x), \int_{R^*(x+1)}^{\infty} V(x + 1)h(R)dR - \pi\right\}$$

for $x = x_0, x_0 + 1, \ldots, X - 2, X - 1$, where $V(X) = \int_0^{\infty} R(X)h(R)dR - C(X)$ corresponds to the age X of termination at any current revenue; $R^*(x)$ is the cutoff revenue at age x; $C(x)$ is the cost of keeping the crop until age x; and π is the expected returns of one week as the system

operates for a long period of time [see discussion of equation (6c) below]. This set of equations (5) is best explained by their first-order conditions. The solution of the set of equations (5), which contains the optimal policy of harvesting the given shrimp pond, will define a unique vector of cutoff revenues, $R^*(x_0)$, $R^*(x_0 + 1), \ldots, R^*(X - 1)$ such that

$$(6)\quad R^*(x) - C(x) = M[R^*(x + 1), (x + 1)] - \pi + H_{x+1}\{M[R^*(x + 2), (x + 2)] - \pi\} + \ldots + H_{x+1}H_{x+2}\ldots H_{X-1}\{M[R^*(X) = 0, X] - \pi\},$$

where

$$(6a)\quad M[R^*(x), x] = \int_{R^*(x)}^{\infty} R(x)h(R)dR - c(x)$$

$$\text{given}\quad H_x = \int_0^{R^*(x)} h(R)dR$$

for $x = x_0, x_0 + 1, \ldots, X - 2, X - 1$,

$$(6b)\quad M[R^*(X) = 0, X] - \pi = V(X) - \pi$$

given $H_X = 0$, and

$$(6c)\quad \pi = \frac{M[R^*(x_0), x_0] + H_{x_0}M[R^*(x_0 + 1), x_0 + 1] + \ldots + H_{x_0}H_{x_0+1}\ldots H_{X-1}M[R^*(X) = 0, X]}{(1 - H_{x_0}) + 2(1 - H_{x_0+1})H_{x_0} + 3(1 - H_{x_0+2})H_{x_0+1}H_{x_0} + \ldots + (X - x_0)H_{X-1}H_{X-2}\ldots H_{x_0+1}H_{x_0}}.$$

Equation (6) states that after deducting $C(x)$, the cutoff revenue at a given age, $R^*(x)$, is determined such that it equals the conditional net expected returns of the shrimp crop from age x to the termination age, X, of the specific shrimp pond. Thus, for example, the last term on the right-hand side (RHS) consists of the product of the probability of a crop at age x to reach the age of $(X - 1)$ times the net returns at the terminal age X. The term "net" [for the RHS of (6)] is used since the opportunity costs of deferring the harvest for one week, π, are deducted from the conditional expected return of each of the following weeks of operation.

In (6a), the conditional expected return at any given age, x, is defined over the domain of 'Sell,' while H_x is the conditional probability to delay harvest for another week of a crop that reaches age, x. Condition (6b) is a transversality condition stating that at the age X the shrimp producer will harvest and sell at any current revenue, i.e., $H_X = R^*(X) = 0$. In (6c) the numerator of π measures the expected return per crop up to age X and the denominator measures the expected life of the crop.

As in the general case [see eq. (1)], the distribution of revenue in the homogenous case [eq (4)] may depend on an univariate distribution o the price or the weight, or on a bivariate distri bution that depends on both:

$$(4a)\quad R_n(x) = W(x)P_n(x), \text{ or}$$

$$(4b)\quad R_n(x) = W_n(x)P(x).$$

Thus, in the case of (4a), only prices are randon and the growth relations are deterministic. Th optimal solution will define a unique vector o cutoff prices, for each age a $P^*(x)$, such that i the current price, $P_n(x)$, is lower than the cutof price, $P^*(x)$, the crop should be kept for anothe week; otherwise, the crop should be harveste and a new crop begun. The negative relation ships between the cutoff prices and the age o the stock have been proved by Hochman.

In the case of equation (4b), where the weigh is random and prices are given and fixed for eac age, the optimal policy will consist of a vecto of cutoff weights, $W^*(x)$, that replace the vecto of cutoff prices, $P^*(x)$. Thus, if the averag weight of the shrimp in the pond, $W_n(x)$, is large than or equal to $W^*(x)$, the current crop shoul be harvested and a new crop started; otherwise the grower should wait another week and checl to see if $W_n(x + 1) \geq$ or $< W^*(x + 1)$, and s on.

In (4), the general case of the homogenou model is when both weight and price are sto chastic. If the weights and prices are indepen dently distributed, the vector of cutoff revenue $R^*(x)$ has the same properties as those of th previous vectors $P^*(x)$ and $W^*(x)$.[2]

The decision process can be described a Markovian. In the homogenous case, it is an er godic Markov chain. Each strategy chosen b the shrimp producer determines simultaneousl the cutoff revenue $R^*(x)$, the transition proba bilities H_x and the immediate reward. Moreover because H_x has a one-to-one correspondence witl the cutoff revenue, at each age one and only on decision variable determines the strategy taken H_x defines the transition probability matrix a follows:

[2] A formal proof of the random price case can be found in Hocl man. The same rationale can be extended to the random weight an the more general random revenue cases.

(7)
$$T = \begin{bmatrix} 1-H_{x_0} & H_{x_0} & 0 & .. & 0 \\ 1-H_{x_0+1} & 0 & H_{x_0+1} & .. & 0 \\ \vdots & \vdots & \vdots & .. & \vdots \\ 1-H_{X-1} & 0 & 0 & .. & H_{X-1} \\ 1 & 0 & 0 & .. & 0 \end{bmatrix}.$$

T is a complete ergodic Markov chain, with steady state probabilities, q_x, to be at a given age group such that,

(8)
$$\pi = \sum_{x=x_0}^{X} M[R^*(x), x]q_x, \text{ and}$$
$$\sum_{x=x_0}^{X} q_x = 1.$$

The General Model-Interseasonal Effects

The solution for the general model described in equation (2) consists of fifty-two vectors of cutoff revenues, $R^*(x, t)$. The Markov chains are no longer completely ergodic, so the steady-state probabilities depend on the initial state. In this case, randomness of prices and weights may also be introduced separately and simultaneously. The optimal policies will take into account the new dilemma the shrimp producer faces, i.e., to sell the crop and enter a new season with a young stock, or to keep the old crop and enter the new season with an old stock. Each of the weekly vectors can be interpreted as in the homogenous case. The negative relations between the cutoff revenues and the age of stock still hold. Moreover, as an approximation, one may derive the steady-state probability and the corresponding π for each of the weekly vectors assuming the conditions of this week will hold for the rest of the period.

An Operational Discrete Model

The basic functional equation (2) can be rewritten in a form manageable for computational purposes, where the continuous distribution is approximated by a histogram of J-equal probability rectangles to yield

(9)
$$g_n(x, t) = \max \begin{bmatrix} S: R_j(x, t) - C(x) + E_R[g_{n-1}(x_0, t-1)] \\ K: E_R[g_{n-1}(x+1, t-1)] \end{bmatrix}$$

for $j = 1, 2, \ldots, J$; $x = x_0, x_0 + 1, \ldots, X - 1, X$, and

$$t = \left\{ \begin{array}{ll} 1, 2, \ldots, 13 & \text{(fall season)} \\ 14, 15, \ldots, 26 & \text{(winter season)} \\ 27, 28, \ldots, 39 & \text{(spring season)} \\ 40, 41, \ldots, 52 & \text{(summer season)} \end{array} \right\},$$
$$J = 20, X = 15,$$

where

$$E_R[g_{n-1}(x, t)] = \frac{1}{J} \sum_{j=1}^{J} g_{n-1}(x, t)$$

for $x = x_0 + 2, x_0 + 3, \ldots, X - 1$, and

$$E_R[g_n(X, t)] = \frac{1}{J} \sum_{j=1}^{J} R_j(X, t) - C(X) + E_R[g_{n-1}(x_0)].$$

Equation (9) serves as the basis for the search through all possible current states for the optimal policies. The efficiency of the algorithm is achieved by making use of the recursive characteristics of the solution following three nested loops: (*a*) At a given week for a given age of the crop, the search for the cutoff revenue is done by approximating the revenue distribution by twenty revenues of equal probability, i.e., .05 for each revenue.[3] The search starts from the highest revenue downward, stopping at the first revenue that results in a decision to keep the crop for another week. Obviously, for any revenue below it (above it) the decision is to keep (sell) the crop. (*b*) The search moves then to the next younger crop at this week and the solution of the relevant cutoff revenue is obtained through the first loop. The second loop continues until all possible ages are considered, and then the search moves to the third loop. (*c*) The preceding week is introduced and the first and second

[3] The respective distributions of prices and weights approximated by dividing the area under the distribution curve into a histogram of 20 equal probability rectangles. Thus, the values corresponding to $j = 1, 2, \ldots, 20$ in equation (12) for the case of random prices [or equation (11) for the case of random weights] are assigned in a monotonic increasing order such that the value corresponding to 1 (20) is the lowest (highest) value from the equal probabilities array of prices (or weights). For the case of random revenue, the 20 values of the array of equal probabilities revenues from the bivariate distribution is obtained from a discrete joint probability table, where the rows are the 20 prices and the columns are the 20 weights. Thus, each of the 400 values of revenue (equal to price times weight combination) has an equal probability of 1/400. The four hundred possible revenues are arranged in an ascending order according to their values, so that they can be used to generate the revenue index $j = 1, 2, \ldots, 20$ of the ascending values of equal probability of .05.

loops are repeated. The third loop continues until all the weeks in the year (52 weeks) are exhausted. Then the same process is followed during the preceding year through the three loops. Starting from the third year, the fifty-two vectors of cutoff revenues in the last two consecutive years are compared and the search process stops when the optimal policies are identical.

The same algorithm is used for both the random price and random weight cases, where the critical values are the cutoff prices and cutoff weights, respectively. The solution algorithm has been programmed in Pascal on an IBM personal computer.[4] Convergence generally requires a few minutes and three to six iterations. The solution consists of the simulations of invariant optimal policies for the fifty-two weeks of an annual production and marketing plan. An empirical example of the model's use is presented in the next section.

Optimal Scheduling of Production and Marketing in a Shrimp Producing Farm in Hawaii

Scarcity of land and high labor costs dictate intensive shrimp production in Hawaii. Early failures in Hawaiian shrimp production demonstrate the need for advanced technologies and management. This section demonstrates how the conceptual framework of the preceeding section can be used as a managerial analysis tool, with particular reference to the round pond technology at the Oceanic Institute in Hawaii.

The Oceanic Institute constructed an experimental intensive shrimp pond at Makapuu in 1985. The pond incorporates features from intensive systems from around the world. It is round in shape, 1 meter deep, slightly sloped to the center, 337 square meters in area, and has a large center sump/drain. The sides of the pond are cement block and the bottom is compacted dirt. A paddle wheel aerates and mixes the pond water in a circular pattern that causes organic wastes to accumulate in the center drain for disposal.

Seven production trials have been conducted since 1986. The Ecuadorian white shrimp, *Penaeus vannamei*, was selected for the trials because of excellent growth characteristics, disease resistance, and high market value. The trials were stocked with animals from 0.7 to 1.56 grams at densities ranging from 45 to 150 animals per square meter. Survival ranged from 78% to 98%, and feed conversion efficiency ranged from 2:1 to 3:1. The animals were harvested at sizes from 15.1 to 26.1 grams (Wyban, Sweeney, and Kanna). These trials provided biological growth estimation data for this study.

Estimated Growth Relationship

Several growth relationships (linear, quadratic, logistic, and log-reciprocal) were tried. The most plausible form was the log-reciprocal:

$$W = e^{\alpha_0 - \alpha_1(1/x)}, \tag{10}$$

i.e., $dW/dx = \alpha_1 W/x^2 > 0$ and $d^2W/dx^2 \geq$ or ≤ 0 with an inflection point at $x = \alpha_1/2$.

The following equation was estimated in order to take into account temperature and stocking density effects on the growth coefficient, α:

$$\ln W = 4.59 - \underset{(32.20)}{238.25(1/x)} + \underset{(4.42)}{18.53DT(1/x)} + \underset{(1.16)}{5.72DD1(1/x)} + \underset{(2.34)}{14.53DD2(1/x)}, R^2 = 0.96, \tag{11}$$

where W is the average weight of the animal in grams; x is the animal age in days; DT is a dummy variable that takes the value of 1 for temperature greater than or equal to 26° C and 0 otherwise; $DD1$ and $DD2$ are dummy variables for density effects representing stocking densities of 100 and 75 animals per square meter, respectively; and numbers in parentheses are t-statistics. When $DD1$ and $DD2$ are both set to zero, it represents stocking density of 150 animals per square meter.

This log-reciprocal equation implies an asymptotic weight level of 98 grams and allows for varying growth rates. The influence of temperature was significant as shown in equation (11), and was applied later in deriving the two seasonal semiannual growth periods. The estimated relationship also indicated that higher stocking density would depress growth. A plot of the actual growth versus the predicted growth at 100 animals per square meter (used in the following analysis) for the two seasonal growth periods is presented in figure 1. These estimated

[4] The algorithm and the computer program are available upon request from the authors.

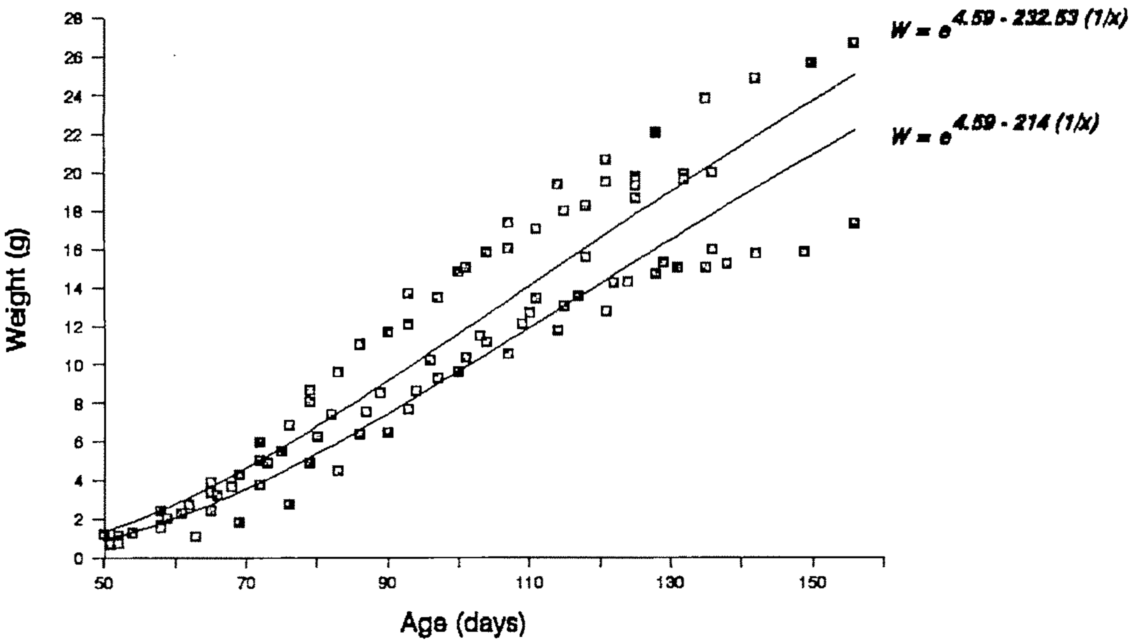

Figure 1. Shrimp growth functions

(12)

$$P = -0.008 + \underset{(37.05)}{0.161W} - \underset{(11.30)}{0.0008W^2} + \underset{(0.02)}{0.0006DS} + \underset{(6.02)}{0.200DF} + \underset{(2.85)}{0.0928DW}, \quad R^2 = 0.96, \quad \text{D-W} = 1.75,$$

growth relationships were used for predicting the weight-age relationship and estimating the random spread. The estimated standard deviation of 1.192 grams/animal was used to derive the univariate normal weight distribution, $h(W)$, and the bivariate normal revenue distribution, $h(R)$.[5]

Estimated Price-Size Relationship

The main market for Hawaiian shrimp producers is the U.S. mainland. Hawaiian producers are price takers in the mainland market. Weekly shrimp prices by size for the year 1985 were obtained from a weekly summary of Penaeid exvessel prices, headless, shell on, from National Marine Fisheries Service *Fishery Market News Reports* (U.S. Department of Commerce).

The size data were adjusted to weight data (there is one-to-one correspondence between size and weight), and were used in estimating the price-weight relationships, allowing for seasonal effects, as follows:

[5] The standard deviation (error) of the equation was chosen as a measure of risk rather than the total sampling variability which is composed of the equation error and the error in estimating the unknown parameters.

where P is price per pound; W is mean weight of size category in gm/animal; DS is a dummy variable for summer; DF is a dummy variable for fall; DW is a dummy for winter; D-W is the Durbin-Watson d-statistics, and numbers in parentheses are t-statistics.

No heteroskedasticity (higher price variance associated with higher weight) was found in this case. The estimated standard deviation, \$0.2625 per pound, was used to construct the price density function, $h(P)$, and the revenue function, $h(R)$.

Estimated Growout Operation Costs

The estimated costs figures are based on the OI round pond farm calculations. They were based on a hypothetical farm of twenty-four ponds, 0.2 hectare (0.5 acre) each with stocking density of 100 animals per square meter.

The feed intake assumed feeding rates based on wet weight of shrimp. Feed costs were calculated at \$0.00125 per gram of feed. Labor costs were calculated at \$203 per week per pond for regular sampling and feeding. Energy costs were calculated at \$56 per week per pond. Stocking

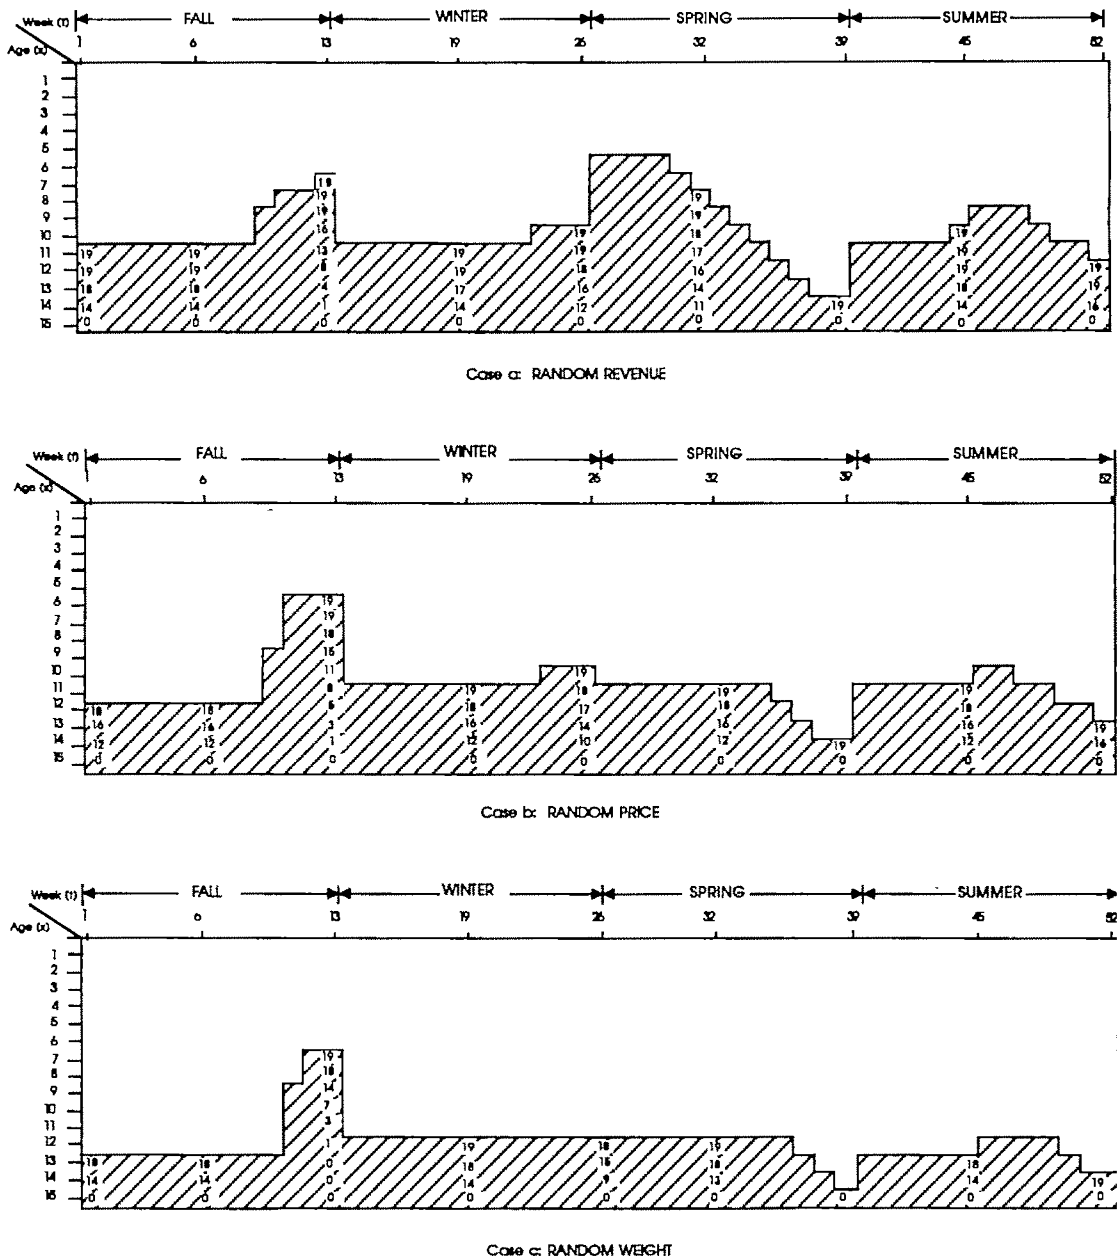

Figure 2. Inter- and intraseasonal optimal policy

costs were calculated at $3,000 per pond, for buying post larva and feeding it in a nursery for sixty-five days. The immediate net return at time t and age x can be defined as

$$P(x, t)W(x, t) - C(x, t),$$

where $C(x, t)$ is the sum of feed cost, labor cost, and energy cost up to age x plus the stocking cost.

Results: The Optimal Policies

The three graphs in figure 2, depict optimal policies for random revenues where both prices and weights are random, (2a), random prices, (2b) and random weights, (2c). The optimal policies are represented by an ordinal scale of cutoff values from 0 to 20 of equal probability for each week of the year and shrimp ages one to fifteen

weeks. The closer the number is to twenty, the higher the cutoff value and the higher the probability of postponing harvesting to the next week, a keep situation. For any given week the numbers will approach a sell situation (0), as the age of the shrimp increases to fifteen, the maximum allowable age. The cutoff value twenty is shown as blank in the graphs representing a keep decision always and the cutoff value zero represents a sell decision always.

Fall and summer have been assigned the growth relationship associated with temperatures above 26° C, while winter and spring have been assigned the growth relationship associated with temperatures below 26° C. Fall is the best season, with higher prices (about 40¢ per kg more on the average) and the best rates of growth owing to relatively higher temperatures. Next best is summer, with the same rate of growth (temperatures) as fall. The least favorable growth and market conditions occur in winter and spring.

The shapes of the frontiers in figure 2 are valuable in depicting interseasonal and intraseasonal trends in the optimal policies. Planned sales are higher in the fall, with the peak at the end of the fall to take full advantage of favorable prices at Christmas. The recommended optimal policy is to postpone harvesting during the last weeks of spring in order to use the favorable growth conditions during the summer. This tendency is strengthened by increased harvesting early in spring to increase capacity for younger crops by the end of spring and beginning of summer.

Table 1 depicts the invariant probabilities to sell for the corresponding optimal policies (i.e., corresponding cutoff values) in selected weeks for the three cases: random revenues (prices and weights), random prices, and random weights. The convergence to the invariant solutions was relatively fast (3–4 iterations), and the reported numerical values of the sell probabilities allow further insight into the detailed seasonal policies.

In table 2 the last week of fall (week 13) was selected to demonstrate the connection between the corresponding cutoff values and their corresponding probabilities on the histogram for a stock at a given age. In the case of random revenues, twenty rectangular histograms were calculated approximating the corresponding bivariate normal distribution for prices and weights for each age. For each of the twenty rectangles there is one value of cutoff revenue and its sell probabilitiy, i.e., the probability that the current revenue at this week for this age will be higher than the assigned cutoff revenue. For example, at the age of eight weeks a cutoff revenue of $109 per 1,000 animals corresponds to 0.05 probability of harvesting (i.e., 0.95 probability of waiting for the next week). Although ages seven, eight, and nine have the same probability to sell of 0.05, their cutoff revenues are different. In fact, the cutoff revenues are monotonically nondecreasing with age. Similarly, histograms of twenty rectangles for the normal price distribution at each age were approximated (the case of random price). At the age of ten weeks a 0.45 probability of selling (0.55 probability of waiting for the next week), corresponds to a cutoff price of $6.38 per kilogram. Because the average weight of a ten-week old animal in the last week of fall is 18.5 grams, the cutoff revenue, which corresponds to the $6.38 cutoff price, is $118 per 1,000 animals. The same can be traced for the third case of random weights with deterministic prices.

If the thirteenth week represents the rest of the year, i.e., the homogenous model, one may calculate the conditional expected net profit per week, π, as well as the expected length of the production cycles. However, given seasonal variations both in prices and weights, there are different policies over the various weeks. Even though the optimal policy patterns for the fifty-two weeks of the year can be calculated in advance, the long-run steady state probabilities and the resulting expected net profits cannot be calculated in a straightforward way as in the nonseasonal case. They depend on the vector of initial stocking dates.[6] The optimal solutions supply the producer with a priori, normative guidelines, but the actual realized policies may follow numerous trajectories. This motivated tracing the actual behavior of the OI shrimp farm during a specific year.

Simulation of the Shrimp Operation Using the 1986 Prices

The case of random prices with deterministic growth relationships was used to trace the behavior of the hypothetical shrimp farm facing the actual prices reported in the National Marine Service market news reports of 1986 (U.S. Department of Commerce). Table 3 shows the sequence of optimal actions assuming the starting date is the first week of fall. For example, at

[6] The Markov chain is not a complete ergodic one, but has periodic cycles.

Table 1. Probabilities to Sell for Selected Weeks of the Optimal Policies

the beginning of week ten, in the fall, the age of the shrimp is nine weeks with an average weight of 16.80 grams. The optimal policies derived in the previous section show a cutoff price of \$6.60 per kilogram. Comparing this number with the actual shrimp price (of \$8.89/kg) during the same period in the year, the decision is to sell the crop since it is more than the cutoff price. If the current market price is less than the cutoff price, a keep decision is recommended. In this case, a keep decision is recommended for all shrimp ages of less than nine weeks old. In other cases, a keep decision can result from a comparison of current market price and cutoff price. In the present case, the pond will be rested for two weeks (weeks 10 and 11) for cleaning. A new stock will then be introduced and the keep-sell decision will be determined as discussed above for another cycle. This tracing is done for one full year, as shown in table 3. This tracing produces 4.00 crops (in a year) with an average harvesting weight of 19.60 grams. The annual net profit is estimated to be \$203,269 for the hypothetical farm with twenty-four round ponds, 0.2-hectare each.

Table 4 summarizes the results of tracing four different cases according to starting dates at the first weeks of each of the four seasons. The operation that starts at the first week of summer yields the highest net profits, \$328,982 per year

for the twenty-four ponds. It has on the average the highest marketing age (and weight) and receives therefore the highest price. The operation depends on the performance during all four seasons, and starting in the summer allows for the best management policies. Other starting dates may involve the loss of $69,000 to $149,000 as compared to operation starting in summer. However, such comparisons do not take into account labor constraints. There is a peak load problem in allocating the labor needed for harvesting if all ponds are started at the same date in summer.

Equally spaced harvests at age eleven weeks (4 crops per pound) is the other extreme. This allows ninety-six harvests per year, which is approximately two harvests per week. The strategy wil result in a loss of $3,750, operating in 1986 (see table 4, fixed scheduling). A hybrid strategy that starts in the summer and uses fixed scheduling, marketing at age thirteen weeks, would result in a net profit of $174,534. The

Summer	11.50	20.99	4.14	9.91	410,761

difference is the shadow price of a labor constraint.

This conceptual framework is helpful in answering another important question often asked by the farmer: How much should I invest in the new technology? As an example, the researchers at OI are interested in the possibility of creating a controlled environment at a constant high temperature of 28° C. To address this possibility the tracing procedure used in obtaining the results in table 4 was rerun assuming summer conditions (>26° C) during the whole year. The results are reported in table 5, indicating an increase in annual net profit of approximately $150,000 on the average in comparison to operation under the existing environmental constraints.[7] This provides the upper limit of the annualized investment cost.

Concluding Comments

A dynamic decision model has been developed to determine the optimal stocking and harvesting strategies of a shrimp-producing pond. The model captures both the dynamics of the decision process and the risk involved. Risk is represented by randomness in market prices and growth of shrimps. The model provides a set of optimal policies for each calendar week of a year and for each given age of the growing shrimps. This model was applied to analyze the economics of the round pond technology recently developed at the Oceanic Institute in Hawaii. By using the management tool developed here, a hypothetical operation can increase its profitability about twofold as compared to fixed scheduling schemes. This surplus profit can be used to invest in the control of environmental quality as well as to alleviate shrimp health problems which may arise as a result of using intensive technology such as the round pond. The model developed here can be adapted and applied to any shrimp farming technology.

The model is an important base for further work in a complete farm setting where hatchery capacity and labor availability can be constraining factors. This model can also be successfully adapted to other growing crops if they are homogenous and production is of an all-in–all-out nature.

[Received October 1988; final revision received August 1989.]

[7] Although the average harvest age of shrimp and thus the average weight and cycles are the same in table 5, the individual crops have different harvest ages and weights. It is coincidental that the averages are identical.

Informational Efficiency of Markets for Stumpage

Courtland L. Washburn and Clark S. Binkley

This paper examines the weak-form informational efficiency of markets for pine sawtimber stumpage in the U.S. South. Analyses of annual and quarterly rates of price change generally indicate that stumpage markets are efficient. When viewed over monthly intervals, stumpage markets do not pass the tests for weak-form efficiency. This failure is attributed to friction in the market due to the time and cost involved in consumating timber sales. The results have implications for price-responsive timber harvest scheduling, for the application of asset pricing models to forestry investments, and for policies governing sales of timber from public lands.

Key words: informational efficiency, market model, stumpage markets.

Are markets for stumpage informationally efficient (Samuelson 1965, Fama 1970)? This question attends several of the most important problems in forest economics. Stumpage market efficiency is a maintained, yet untested, hypothesis in most econometric analyses of timber supply (e.g., Berck, Adams and Haynes). Recent applications of the capital asset pricing model to forestry investments (e.g., Thomson; Binkley and Washburn 1988a, b; Redmond and Cubbage) assume that stumpage markets are efficient. Conversely, several recent papers rely on predictable departures from equilibrium price levels—market inefficiency—to argue that timber owners can make economic gains by adopting marketing policies which exploit stochastic variations in stumpage prices (Norstrom, Brazee and Mendelsohn 1988b, Lohmander 1988).

This paper examines the informational efficiency of markets for sawtimber stumpage. We determine whether the current price of sawtimber stumpage incorporates all of the information obtainable by studying past departures from equilibrium rates of price change. This is known as a test of "weak-form" market efficiency (Fama 1970).

In the next section the theory of storage (Working 1948, 1949; Brennan; Telser) is used to derive a rational expectations equilibrium (Muth, Kohn, Scheinkman and Schechtman) for stumpage markets. In equilibrium, the current price of stumpage will equal its expected future price, less expected capital costs and storage expenses (e.g., land rental and protection from fire and pests) plus the expected value of its physical growth. If new information alters expectations, then stumpage flows in or out of storage until the equilibrium is restored. As long as the store of stumpage is never exhausted and can be freely expanded or contracted, stumpage prices will never depart from equilibrium levels. Maintenance of the rational expectations equilibrium ensures that stumpage markets are informationally efficient.

The usual tests for weak-form market efficiency are conducted on time series of differences between actual and equilibrium rates of stumpage price change. Efficient markets are expected to produce white-noise deviations. This implies that departures from equilibrium rates are serially independent. We calculate two measures of serial dependence. The first, more common measure, is an autocorrelation function comprised of serial correlation coefficients. But parametric tests of serial dependence can reject the market efficiency hypothesis either because markets are indeed inefficient or because of incorrect parameterization of the underlying stochastic process. To bolster the results, a non-

This research is part of a larger project on the evaluation of investments in southern pine forestry which is sponsored jointly by Yale University, the USDA Forest Service Southeastern Forest Experiment Station, Scott Paper Company, Weyerhaeuser Company, South Carolina National Bank, and First Wachovia Bank and Trust.

The authors wish to thank two anonymous *Journal* reviewers for many useful comments on earlier drafts. None of these organizations or individuals is responsible for the data, analysis, or conclusions presented here.

parametric test based on the number of turning points in the series is also conducted. Both tests are modified to account for the way stumpage price data are averaged within reporting periods. The tests are described in the second section below.

The analysis is confined to sales of private southern pine timber. Private sales were studied because prices reported for stumpage sold on national forests and other public lands are bid prices that are likely to reflect expectations of future prices rather than current market values.[1] The analysis was restricted to southern pine timber because prices from private sales of the other commercially important species of sawtimber stumpage—softwoods in the western United States such as Douglas-fir and western hemlock—are not publicly available. Even with these limitations, many series of sawtimber stumpage prices are available for study. We work with eighteen series, reflecting monthly and quarterly as well as annual observations.

Markets for southern pine sawtimber stumpage pass the tests for weak-form efficiency when viewed on an annual or quarterly basis but not necessarily when monthly returns are considered. The paper's final section discusses the implications of these results for price-responsive harvest scheduling, for the estimation of forest asset pricing models, and for policies governing the sale of timber from public lands.

A Model of Informationally Efficient Stumpage Markets

The theory of storage (Working 1948, 1949; Brennan; Telser) provides our rational expectations model of stumpage market equilibrium. Storage theory was developed to explain the storage of agricultural commodities. The theory postulates that owners of a storable good will withhold it from the market if they anticipate a price increase greater than storage and capital costs. Similarly, they will remove the commodity from storage if its current price is higher than its expected future value. Aggregated over all commodity owners, this behavior produces a rational expectations equilibrium in the commodity market (Muth, Samuelson 1971, Kohn Scheinkman and Schechtman). As long as there is a positive amount of the commodity in storage, the equilibrium is characterized by the following relationship between current prices and expected values:

$$(1) \qquad P_t = E_t[(P_{t+1} - c_t) \exp(-r_t)],$$

where P_t and P_{t+1} are per-unit commodity prices at the beginning of periods t and $t + 1$ respectively, c_t is the cost of warehousing the marginal unit under storage during period t (for convenience it is assumed payable at the end of the period), and r_t is the capital cost of holding the commodity during period t (alternatively, r_t can be viewed as the rate of return required by investors to hold the commodity).[2] E_t is the expectations operator conditioned on information available at the beginning of period t.

To adapt storage theory to stumpage, we express holding costs as a proportion of stumpage price and incorporate into the equilibrium relation the physical growth of the marginal unit of the stumpage store:

$$(2) \qquad P_t = E_t[P_{t+1} \exp(g_t - c_t - r_t)],$$

where P_t and P_{t+1} are per-unit stumpage prices at the beginning of periods t and $t + 1$ respectively, g_t is the growth rate of the marginal unit of stumpage in storage, c_t is the cost of storing the marginal unit during period t (e.g., land rent and protection from fire and pests), and r_t is the capital cost of holding stumpage during period t. This rational expectations equilibrium will hold and stumpage markets will therefore be informationally efficient, as long as (*a*) the store of stumpage is not exhausted and (*b*) movement of stumpage in and out of storage is frictionless.

For this analysis, variation in the marginal rate of growth minus storage cost ($g_t - c_t$) is assumed negligible over the operational size range of the stumpage store. Although some researchers might argue against such an assumption (e.g. Brazee and Mendelsohn 1988a; Schworm, Hoaas and Hyde; Boyd and Hyde), it is justified here on several grounds. First, the operational size

[1] Purchasers of public stumpage are usually given several years to harvest their timber. Payment is not made, aside from a small deposit, until the timber is harvested. (Since 1986, the Forest Service has required payment for one-half of the timber by the midterm of the contract.) Thus, buyers of public stumpage will base their bid on the stumpage price they expect to prevail on the probable harvest date (which could be several years in the future) rather than on the current stumpage price. We thank an anonymous reviewer for making this point.

[2] In this formulation, the cost parameter c incorporates the "convenience yield" of storage (Kaldor). Convenience yield was proposed to account for "inverse carrying charges," the empirical observation that commodities are stored even when the costs of storage appear to outweigh the benefits. The flexibility that a stockpile of the commodity gives processors to respond to changes in product demand is the most commonly cited origin for the convenience yield

of the stumpage store is likely to vary over a rather narrow range. In the southeastern United States, for example, the net change in the stock of southern pine sawtimber stumpage was only 0.1%, 1.5%, 2.1%, 1.7%, and 0.4% in the years 1952, 1962, 1970, 1976, and 1984, respectively (USDA Forest Service). Second, any change in marginal growth rates that might occur as the stumpage store contracts or expands will be at least partially offset by a change in marginal storage costs. Consider, for example, a decrease in the size of the stumpage store. The marginal growth rate might increase if marginal harvests shift to younger stands of timber. However, younger timber occupies more land per unit of stumpage. Presuming that storage costs depend on land area, the costs per unit of stumpage would increase and thus offset the increase in marginal growth. Finally, a large part of the southern pine stumpage store is held by nonindustrial owners—individuals whose primary purpose of land ownership may not be timber production. (According to the USDA Forest Service, in 1984 nonindustrial owners held 63% of the southern softwood inventory.) For a variety of reasons, relatively high prices may be required to draw their timber into the market. Much of the timber they hold might be overmature in the sense that its rate of growth minus storage cost is smaller than at the margin of the stumpage store. Thus, as stumpage prices fluctuate about the "reservation" price of these nonindustrial owners, their timber is drawn in and out of the market without altering the value of $g_t - c_t$. As shown in the next section, the assumption that $g_t - c_t$ is constant allows the market efficiency tests to be conducted without data on growth rates and storage costs.

Expressing $g_t - c_t$ as a constant proportion (d) of per-unit stumpage price, the equilibrium condition becomes

$$(3) \qquad P_t = E_t[P_{t+1} \exp(d - r_t)].$$

Or, in terms of the rate of stumpage price change during period t (R_t):

$$(4) \qquad E_t[R_t - (r_t + d)] = 0.$$

If this rational expectations equilibrium is always satisfied, then stumpage markets are informationally efficient.

A Test of Informational Efficiency

Tests of the informational efficiency of markets seek to accept or reject an hypothesis that all relevant information is reflected in market prices, or, equivalently, that the current market price is the best estimate of any future discounted value. Before such tests can be conducted, the set of relevant information must be identified. Specifically, the expectations operator in relationships (3) and (4) must be conditioned on an identifiable information set.

Financial economists have traditionally used three categories of information to test market efficiency. Markets are weak-form efficient if they correctly incorporate information obtainable by studying historical prices, semistrong-form efficient if they reflect all publicly available information, and strong-form efficient if they account for both public and private information (Fama). The information categories are nested so that rejection of weak-form efficiency implies rejection of semistrong- and strong-form efficiency as well.

Empirical analyses of markets for financial assets have consistently supported weak-form efficiency, usually supported semistrong-form efficiency, but rarely supported strong-form efficiency (Malkiel). Efficiency tests of markets for real assets have been much less extensive. Analyses to date have generally supported the weak-form efficiency of markets for commercial and residential real estate (e.g., Gunterman and Smith), precious metals (e.g., Solt and Swanson), and agricultural commodities (e.g., Holthausen and Hughes).

Because this study tests the weak-form efficiency of stumpage markets, expectations are conditioned on an information set that consists of past departures from equilibrium rates of stumpage price change. The weak-form efficient condition can therefore be expressed as follows:

$$(5) \qquad E_t[R_t - r_t + d | R_{t-1} - r_{t-1} + d, R_{t-2} - r_{t-2} + d, \ldots] = 0.$$

Or, in *ex post* form,

$$(6) \qquad R_t - r_t + d = error_t,$$

where the expected value of $error_t = 0$ and $\mathrm{cov}(error_t, error_{t+j}) = 0$ for all j not equal to 0. In other words, departures of actual (R_t) from equilibrium ($r_t - d$) rates of stumpage price change are white-noise.

A testable implication of equation (6) is that departures from equilibrium rates of price change are serially independent. That is, past departures from equilibrium cannot be used to identify current departures. A finding of significant serial

dependence is cause to reject a joint hypothesis that stumpage markets are efficient and that equilibrium rates of stumpage price change conform to the specified model (Fama 1976).

That either market inefficiency or a misspecified model of equilibrium price change can cause the serial dependence test to reject the hypothesis is problematic. However, the market efficiency component of the hypothesis can be isolated to some extent by performing the tests with alternative models of equilibrium price change (Brenner). If the test results are robust with respect to the alternative models, then acceptance or rejection of the hypothesis can with greater confidence be attributed, respectively, to market efficiency or inefficiency.

In this analysis, the model of equilibrium stumpage price change depends on the model of capital cost (r_t). Two distinct capital cost models were adopted, each an alternative version of the Sharpe (1963) single-index market model. The market model postulates a linear relationship between equilibrium returns on individual assets and the value of a common market factor, or index, that affects the return on all assets. Alternative indices produce different models for the capital cost of holding stumpage. We selected two indices—returns to the stock market (m_t) and the rate of inflation (i_t):

(7) stock-based market model

$$r_t = a + bm_t + u_t, \text{ and}$$

(8) inflation-based market model

$$r_t = a + bi_t + u_t.$$

The models include a random disturbance term u that has an expected value of 0, is not serially correlated, and has zero covariance with the index.

The rate of return to the stock market is an obvious choice for the index. A stock-based market model is routinely used to explain variation in returns to financial assets. It produces essentially the same results as a capital asset pricing model (Sharpe 1964, Lintner) that uses stock market returns as a proxy for returns to the overall market portfolio.[3]

[3] The CAPM specifies the following relationship: $E_t r_t = rf_t + \beta(E_t M_t - rf_t)$, where rf_t is the risk-free rate of return during period t, and M_t is the rate of return on the overall market portfolio during period t. Although the theoretical bases of the market model and the CAPM are very different (Collins), a market model that uses a proxy for M_t (e.g., stock market returns) as the market index and the CAPM give similar results as long as the risk-free rate of interest is relatively constant over time. Brenner has shown that stock market efficiency tests are insensitive to the choice of one model over the other.

Although an inflation-based model is a less obvious choice than the stock-based formulation, the rate of inflation might be a reasonable index for forest assets. Conventional wisdom is that timber is a good inflation hedge. For example, Redmond and Cubbage (p. 335), suggest that inflationary expectations play a major role in determining the price of stumpage because it is held ". . . as a store of value for times of inflation. . . ." If the real risk-free rate of interest is constant and stumpage holders simply require a constant real risk premium, then the slope coefficient in the inflation-based model will be equal to one. Such a model of equilibrium stumpage price change has been used by Lohmander (1985) to test the efficiency of roundwood markets in Finland, Norway, and Sweden. It is also well known that stock market returns and inflation are inversely related (e.g., Fama and Schwert). Thus, stock-based and inflation-based models of capital cost differ and should provide a good indication of the robustness of serial dependence results to model specification.

The alternative models of equilibrium stumpage price change ($r_t - d$) produced by the two capital cost formulations can be estimated by ordinary least squares regression of realized rates of stumpage price change on realized stock returns or inflation:

(9) stock-based $R_t = \alpha + \beta m_t + \epsilon_t$, and

(10) inflation-based $R_t = \alpha + \beta i_t + \epsilon_t$,

where α is an estimate of the market model's constant term (a) minus the constant rate of stumpage growth less holding costs (d), and the error term ϵ includes the market model's random disturbance term (u).

The residual errors from regressions (9) and (10) represent departures from equilibrium rates of stumpage price change—the error term in equation (6). If the residual errors are serially independent, then stumpage markets pass the test of weak-form efficiency and weak-form information cannot be used to identify departures of stumpage prices from equilibrium levels.

To measure the serial dependence of the departures from equilibrium rates of price change we calculated the autocorrelation function. The autocorrelation function is a standard measure of serial dependence in market efficiency studies. It assumes, however, that the departures from equilibrium rates of price change are drawn from a normal distribution. If the rates are not normally distributed, then the correlation coeffi

cients, and particularly their standard errors, may be misleading. To assess the normality of the rates of change in our analysis, and thus the potential for serial correlation results to produce faulty conclusions, we calculated coefficients of skewness and kurtosis of each series and compared them with the values expected for a normal variate.

In the event that departures from equilibrium rates of stumpage price change are not distributed normally, we also conducted a nonparametric runs analysis for serial dependence called the turning point test (Kendall and Stuart). To conduct the test, the observed number of turning points—any peak or trough in the series—is compared to the number expected in a random series. A positive deviation from the expected number indicates negative serial dependence, and a negative deviation suggests positive dependence.

Interpretation of both serial dependence measures is complicated because stumpage prices are reported as averages of prices observed throughout a measurement interval (e.g, the average price during each calendar year) rather than values at a particular point in time (e.g., the price on 1 Jan. of each year). This averaging induces spurious positive dependence in the rate of price change between successive periods. Working (1960) determined that when rates of change are calculated from averages of random values at equally spaced intervals within a period (e.g., with annual average prices calculated from prices at the close of each month), the induced serial correlation at the first lag quickly approaches 0.25 as the number of intervals within the period increases. No correlation is induced at the second and all subsequent lags.

To the best of our knowledge, the number of turning points expected in an averaged, random series has not previously been quantified. Consequently, we conducted a Monte Carlo study to do so. The analysis is detailed in an appendix available from the authors upon request. In brief, random series were generated, period averages were calculated, and rates of change between successive periods were determined. Serial correlation tests on the rates of change confirmed Working's (1960) result of a correlation coefficient of 0.25 at the first lag and zero at subsequent lags. The number of turning points in the series averaged $(n - 2)0.604$, fewer than the $(n - 2)0.667$ turning points expected in a random series. Based on these findings, we chose as null hypotheses a coefficient of 0.25 at the first lag and zero at all subsequent lags for the serial correlation test, and $(n - 2)0.604$ turning points for the turning point test.[4]

Results

Historical price series were obtained for southern pine sawtimber stumpage sold from private land in the U.S. South. Timber Mart South (TMS) was the primary source. TMS has reported average statewide stumpage prices at monthly intervals since December of 1976. The monthly TMS prices were averaged to produce a comparable set of quarterly series. Other series of quarterly and annual prices were obtained from various state reports. Table 1 gives the reporting source, geographic coverage, measurement interval, and observation period of each series.

The monthly consumer price index (CPI) was used to measure inflation. To be consistent with the averaged stumpage price series, the inflation index was averaged over quarters and years to obtain quarterly and annual measures. Daily closing values of the Center for Research in Security Prices (CRSP) composite index of stocks on both the American and New York exchanges were averaged over months to obtain a monthly index of stock market value. The monthly values were then averaged to obtain quarterly and annual indices. Because the CRSP index dates back only to 1962, values of the Standard and Poor's 500 (S&P 500) index—adjusted by Ibbotson Associates to include reinvested dividends—at the close of each month were averaged to obtain quarterly and annual stock market series for use with stumpage price series that predate 1962.[5]

Rates of change in stumpage price, stock market value, and inflation were calculated as first differences of the natural logarithm of the series. Ordinary least squares regression was then used to estimate stock- and inflation-based models of equilibrium price change—relationships (9) and (10)—for each price series. Table 2 dis-

[4] The reported stumpage prices are not actually averages of prices at equally spaced intervals within periods. Rather, they are averages of sale prices observed at irregular intervals within periods, sometimes weighted by the volume of stumpage in the sale. This sort of averaging will induce the same degree of serial dependence as the averaging of prices at regular intervals within periods as long as the likelihood of a sale occurring and the expected sale volume are constant throughout each period.

[5] From 1962 through 1987, the correlation between quarterly CRSP and S&P 500 returns was 0.944. Thus, the use of different stock market indices should not materially affect the comparison of monthly with quarterly and annual results.

Table 1. Southern Pine Sawtimber Stumpage Price Series

Reporting Source	Geographic Location	Measurement Interval and Observation Period
Timber Mart South	Alabama, Arkansas, Florida, Georgia, Kentucky, Louisiana, Mississippi, North Carolina, Oklahoma, South Carolina, Tennessee, Texas, Virginia	Monthly, Oklahoma and Kentucky 1981–87, all others 1977–87
Louisiana Dept. of Agriculture, Office of Marketing (Annual averages reported in Ulrich)	Louisiana	Quarterly, 1955–87
Mississippi Forestry Commission	Mississippi	Quarterly, 1969–79
Arkansas Forestry Commission (1953–79), Timber Mart South (1980–87)	Arkansas	Annual, 1953–87
South Carolina Forestry Commission (FY 1950–FY 1976), Timber Mart South (FY 1977–FY 1987)	South Carolina	Annual, FY 1950–FY 1987

plays the coefficient estimates. To the extent that stock market returns measure returns to the overall market portfolio, the slope coefficients of the stock-based market model indicate the systematic or undiversifiable risk of holding stumpage. An asset with the same financial risk as the market as a whole has a coefficient equal to 1; the smaller the coefficient, the less the risk. The slope coefficients of the inflation-based model measure the ability of stumpage to hedge against realized inflation. A complete inflation hedge has a coefficient equal to 1.

The market model results are mixed. Monthly rates of change in the price of southern pine stumpage exhibited no significant relationship with inflation rates or stock market returns. On the other hand, the quarterly rates of change calculated from both TMS and Louisiana and Mississippi state reports are related directly, albeit weakly, to stock market returns. Whereas nine of the thirteen slope coefficients in the monthly stock-based model were negative, all of the quarterly TMS slope coefficients were positive. It appears that ownership of southern pine stumpage provides no hedge against inflation, and entails a rather small degree of systematic risk.

Autocorrelation functions of the regression residuals, which represent departures from equilibrium rates of stumpage price change, were estimated to twelve lags for the monthly, eight lags for the quarterly, and four lags for the annual price series. The results for the stock-based residuals are presented in table 3 and for the inflation-based residuals in table 4. Because period averages were used to calculate rates of price change, the null hypothesis of no serial dependence, and weak-form market efficiency, is a correlation coefficient of 0.25 at the first lag and 0 at all further lags.

The monthly departures from equilibrium rates

Note: An asterisk (*) indicates that the correlation coefficient is two standard errors from the expected value (0.25 for first lag and 0.0 for all subsequent lags).

for both the stock- and inflation-based models consistently exhibited negative correlation at the first lag (the coefficients were significantly less than 0.25). In states where the relationship at the one-month lag was relatively weak, there was often negative correlation at the two-month lag (e.g., Mississippi, Texas, and Florida). Thus, a departure from the equilibrium rate of monthly price change tended to be corrected the next month by a departure in the opposite direction. The correction sometimes persisted for two months. Plots of the autocorrelation and partial autocorrelation functions indicated that the relationships follow either first- or second-order moving-average processes having memories of only one or two periods, respectively. Thus, studying the past behavior of monthly southern pine prices can help predict future departures from equilibrium rates of price change, but for only one or two months in advance.

The serial dependence in the monthly residuals is largely eliminated when departures from equilibrium rates of change are examined over quarters. Although nearly all of the quarterly series calculated from monthly Timber Mart South prices retained their negative correlation at the first lag (the coefficients were less than 0.25), only the coefficients for Kentucky were statistically significant. Among the quarterly and annual series reported by state agencies, only the quarterly Mississippi prices exhibited a negative correlation at the first lag. It appears that studying departures from equilibrium rates of price change over quarters or years can not help to predict future quarterly or annual departures.

There is, however, cause to be wary of the

serial correlation results. Calculation of skewness and kurtosis measures for each series of regression residuals indicated that most of them are not normally distributed. Many of the distributions are skewed (in some cases to the right and in others to the left). Even more are leptokurtotic (fat-tailed); that is, there were larger numbers of relatively large deviations from expected changes than would occur for a normal distribution. This apparent lack of normality implies that the results of the serial correlation tests may be misleading and should be validated with the nonparametric turning point tests.

Table 5 compares the observed number of turning points in each series of regression residuals with the number expected from an averaged, random series. The turning point test was less likely than the serial correlation test to reject market efficiency. For example, whereas the serial correlation test rejected market efficiency for twelve of the thirteen series of monthly stock-based residuals, the turning point test rejected efficiency for only four of the thirteen series. However, in general the turning point results confirm the results of the serial correlation analysis.

Conclusions

The results of these tests for weak-form market efficiency depend on the time interval over which departures from equilibrium rates of stumpage price change are measured. On annual and quarterly bases, departures from equilibrium rates were serially independent, indicating that stum-

page markets are weak-form efficient. Weak-form information can not be used to produce a better estimate of the price of stumpage a quarter or more into the future than the capitalized current price. On a monthly basis, however, markets for southern pine sawtimber stumpage do not pass this test. A departure from the equilibrium rate of stumpage price change over one month tends to be followed by a departure in the opposite direction during the next month.

It is important to note that the weak-form efficiency test implicitly assumes that movement of stumpage in and out of storage is frictionless; that is, that timber sale plans can be instantaneously adjusted at no cost. This assumption may not be reasonable. The time and cost involved in consumating a timber sale might produce short-run friction in stumpage markets. If this is so, then the failure of stumpage prices to adjust instantaneously to new information such as demand or interest rate shocks might indicate that the costs of adjustment exceed the possible economic gains, not that stumpage markets inefficiently process weak-form information.

These findings have important implications for three areas of forest economics. First, if stumpage markets are weak-form efficient, then there can be no gain from using past price movements to play the market in timing timber harvests. This appears to be the case for southern pine sawtimber if the time required to complete a timber sale is a quarter or longer. If, however, a timber sale can be consumated within a month, our results are less certain, suggesting that price-responsive models of the Norstrom/Lohmander/Brazee-Mendelsohn type for the optimal time to harvest

timber could possibly produce some economic gains. However, data on adjustment costs would be needed for this type of analysis.

Second, the capital asset pricing model assumes that asset markets pass the weak-form efficiency test. If the market for an asset is not weak-form efficient, then the expected return on the asset is not described by the CAPM relationship. Consequently, a CAPM for forest assets based on short-run, monthly data is inevitably misspecified. This specification error might account for the wide differences observed in CAPM parameter estimates derived from monthly and annual data (Binkley and Washburn 1988b).

Finally, for at least thirty years economists have urged the USDA Forest Service and other similar public agencies to alter timber supply in response to changes in stumpage prices. When prices are high, the argument goes, the public timber agencies should offer more timber, and when prices are low, they should withdraw timber from the market. Such a policy would presumably increase public timber revenues, and in markets where the public agencies have monopsony power, would tend to stabilize prices.

Two considerations undermine the implementation of such a policy. First, achieving these putative gains requires that stumpage markets are inefficient; otherwise, there is no way to know if current prices are high or low. Yet, the results of this study indicate that markets for pine stumpage in the South pass the standard tests for weak-form informational efficiency. All of the profits which can be obtained from a price-responsive sales policy on the southern national forests have already been extracted from the system. Prices fluctuate in a socially optimal manner.

Second, even if stumpage markets in other regions are found to be inefficient, the Forest Service has only a limited capacity to influence, in the short run, the amount of timber which is harvested from the national forests (Adams, Binkley, and Cardellichio). The Forest Service sells timber but does not actually harvest it. Typical timber sales contracts provide a period of several years for the purchaser to harvest the sale. As a result of this sales procedure, timber sold by the Forest Service enters an inventory of uncut timber under contract. Within the confines of expiration terms and other contract provisions, purchasers may harvest timber out of this inventory whenever they desire. Altering the quantity of timber sold into the inventory has only an indirect effect on the quantity of timber actually supplied from the national forests in any one year. Consequently, harvest levels are already subject to market forces, and moves to shorten contract length, reduce the size of the inventory of uncut volume under contract, or otherwise limit harvest flexibility could impair the efficiency of stumpage markets. For these reasons, failing to adjust Forest Service sales levels in the face of fluctuating timber prices may not be economically irrational.

Bootstrapping in Applied Welfare Analysis

Catherine L. Kling and Richard J. Sexton

Bootstrapping procedures are used to estimate the statistical properties of common empirical welfare measures. Results from a Monte Carlo experiment indicate that welfare estimates such as Marshallian consumer surplus often exhibit significant bias. Standard errors of welfare estimates are found to often exceed the magnitude of the point estimate for typical cross-section data sets and are generally larger than the difference between comparable Hicksian and Marshallian measures. Precision of welfare estimates can be markedly enhanced through generating larger data sets, obtaining better model fits, and through imposition of innocuous inequality restrictions on the demand function parameters.

Key words: bootstrapping, consumer welfare, Monte Carlo, nonmarket valuation, recreation demand, statistical inference.

This paper investigates the use of bootstrapping procedures to address problems in applied welfare analysis. Although the primary focus is on applications in recreation demand, the methods are applicable to a number of fields. The prototype methodology in applied welfare analysis involves statistical estimation of a demand function or system of demand functions. The estimated model is then used to calculate point estimates of Marshallian consumer surplus or exact Hicksian welfare measures of compensating or equivalent variation. Recommendations for policy or project decision making are based on the value of these point estimates.

A number of different welfare measures are relevant depending upon the type of analysis. For example, the valuation of recreational facilities and amenities requires an estimate of the total area under a demand curve (e.g., Ziemer, Musser, and Hill; Bockstael and Strand). In studies of agricultural policies, industrial organization, and regulation, the welfare effects of a small price change, particularly the deadweight loss, are at issue (e.g., Parker and Connor; Kaiser, Streeter, and Liu).

Welfare measures computed from estimated demand function parameters are random variables with nontrivial and usually unknown probability distributions. This basic statistical fact has become a subject of increasing concern among welfare analysts [Bockstael, Hanemann, and Strand (BHS); Graham-Tomasi, Adamowicz, and Fletcher (G-TAF); Adamowicz, Fletcher, and Graham-Tomasi (AFG-T), and Smith] for two fundamental reasons: (*a*) welfare estimates computed from point estimates of demand are often biased estimators of the "true" welfare (BHS, G-TAF, Smith); (*b*) because the probability distributions of the welfare estimators are usually unknown, it has not been possible to evaluate the statistical reliability of welfare estimates through computation of standard errors or confidence intervals or to make basic statistical inferences including hypothesis tests. In particular, the usual measures of goodness of fit such as R^2 or t-statistics need not imply corresponding accuracy of welfare estimators.

Basing recommendations for policy and project decisions on biased welfare estimates about which no other statistical properties are known does not seem desirable. The goal of this paper is to suggest improvements in this basic methodology using bootstrapping techniques. Bootstrapping permits the assessment of variability in an estimate using only the data at hand by

resampling the original observations. A variation of the bootstrapping methodology has recently been introduced into applied welfare analysis by G-TAF and AFG-T.

This paper illustrates and analyzes the use of bootstrapping to estimate the bias and precision of any empirical welfare measure. The paper extends the work of G-TAF and AFG-T in a number of contexts: (*a*) it uses a bootstrap that resamples from the empirical error distribution rather than from a normal distribution; (*b*) it analyzes a variety of welfare estimators rather than just the Marshallian measure of total consumer surplus; (*c*) it shows how to construct confidence intervals for welfare estimators that are unlikely to be normally distributed; (*d*) it analyzes the bootstrap in a Monte Carlo framework wherein the true values of the welfare measures are known and the performance of the bootstrap can be evaluated in a variety of empirical settings; and (*e*) an adaptation of the basic bootstrap methodology using inequality constraints is proposed and evaluated as a means of reconciling some significant problems raised in the G-TAF and AFG-T analyses.

The next section describes in more detail some basic results concerning the properties of welfare estimators computed from common demand functions. The bootstrap methodology, including the adaptation, is discussed in the following section. The Monte Carlo experiment to illustrate and evaluate use of the bootstrap is then described and analyzed. The paper closes with conclusions and recommendations.

Consumer Welfare Estimators

To make the scope of this study manageable, it focuses specifically upon the linear and semilog demand functions. These are the most commonly used functional forms in recreation analysis [McConnell, Bockstael and Strand (BS)], and both are compatible with utility maximization (Hanemann).[1] However, the problems which motivate this paper and the results we obtain should apply to any utility theoretic demand function.

The demand functions are as follows:

$$(1) \qquad X_i = a + bP_i + cY_i + u_i,$$

$$(2) \qquad X_i = \exp(a + bP_i + cY_i + u_i),$$

where X_i is the quantity consumed of the relevant good by the ith individual, P_i and Y_i are, respectively, a nonstochastic normalized price and the consumer's income. Use of the same parameter symbols for both functions is for convenience and does not imply that the parameters are identical. It is assumed throughout that the u_i are identically and independently distributed with variance σ^2.

Welfare calculations have been alternatively based on the actual X_i or on only the systematic portion, X_i', of demand, where for the linear model,

$$(3) \qquad X_i' = a + bP_i + cY_i = X_i - u_i.$$

Bockstael and Strand provide guidance on the choice between X_i and X_i' based on alternative interpretations of the error term, u_i.

Table 1 summarizes welfare formulas for both the linear and semilog functions based on the actual X_i. Subscripting to denote individuals is omitted from the table and from the subsequent text where appropriate. The small price change for formulas in rows B, C, E, and F is denoted by $k = P1 - P0$, and

$$(4) \qquad X1 = a + bP1 + cY + u.$$

Rows A–C in table 1, respectively, provide the Marshallian surplus formulas for the total consumer surplus, the small price change surplus, and the small price change deadweight loss. Rows D–F provide the corresponding Hicksian compensating variation formulas. Column 2 identifies the graphical depiction of each area in figure 1.

In the usual sampling-theoretic interpretation, a, b, and c are nonrandom parameters and the X_i' are also nonrandom. The actual quantities, X_i, however, are random due to the stochastic error term. It follows then that welfare measures based on the true parameters and the X_i' are nonstochastic under the sampling theoretic interpretation but that measures based on the actual X_i are stochastic (BHS). For example, for the linear demand, the expected true total Marshallian consumer surplus (cs^T) given the parameters a, b, and c is

$$(5) \quad E[cs^T] = \frac{(a + bP + cY)^2 + \sigma^2}{-2b} = \frac{X'^2 + \sigma^2}{-2b}.$$

In empirical work, the parameters a, b, and c, and the disturbance vector $u = \{u_1, \ldots, u_n\}$ must be replaced in table 1 and equations (3)

[1] The double log function is also popular, but it is excluded here in part because the total consumer surplus measure may be unbounded for this function.

Table 1. Alternative Welfare Measures for the Linear and Semilog Demand Functions

Welfare Measure	Fig. 1 Area	Linear	Semilog
A Total *CS* (*cs*)	ABP_0	$\dfrac{x_0^2}{-2b}$	$\dfrac{x_0}{-b}$
B Small *CS* (*CSS*)	P_0P_1CD	$\dfrac{x_1^2 - x_0^2}{2b}$	$\dfrac{x_1 - x_0}{b}$
C *DWL CS* (*CSD*)	ECB	$-\dfrac{k^2b}{2}$	$\dfrac{x_1(1 - kb) - x_0}{b}$
D Total *CV* (*CVT*)	FBP_0	$-\dfrac{b}{c^2} + \exp\left(c\left(\dfrac{-(a + e + c_y)}{b} - p_0\right)\right)\left[\dfrac{x_0}{c} + \dfrac{b}{c^2}\right]$	$-\dfrac{1}{c}\ln\left(1 + \dfrac{c}{b}x_0\right)$
E Small *CV* (*CVS*)	P_0P_1DB	$-\left[\dfrac{b}{c^2} + \dfrac{x_1}{c}\right] + \exp(ck)\left[\dfrac{x_0}{c} + \dfrac{b}{c^2}\right]$	$-\dfrac{1}{c}\ln\left[1 + \dfrac{c}{b}(x_0 - x_1)\right]$
F *DWL CV* (*CVD*)	GDB	$\left[\dfrac{cx_0 + b}{c^2}\right][\exp(ck)(1 - ck) - 1]$	$-\dfrac{1}{c}\ln\left[1 + \dfrac{c}{b}(x_0 - x_1)\right] + \dfrac{kbx_1}{-b + c(x_1 - x_0)}$

and (4) by statistical estimates denoted by $\hat{\theta} = \{\alpha, \beta, \gamma\}$, and $\epsilon = \{\epsilon_1, \ldots, \epsilon_n\}$, respectively, where $\epsilon_i = X0_i - \alpha - \beta P0_i - \gamma Y_i$. Thus,

$$\hat{X}_i = \alpha + \beta P_i + \gamma Y_i. \tag{3'}$$

Because α, β, γ, and, in turn, $\hat{X}$ are random variables, the various welfare estimators are also random variables. Most involve some ratio of random variables regardless of whether X or $\hat{X}$ is used in the calculations. In general, the mean

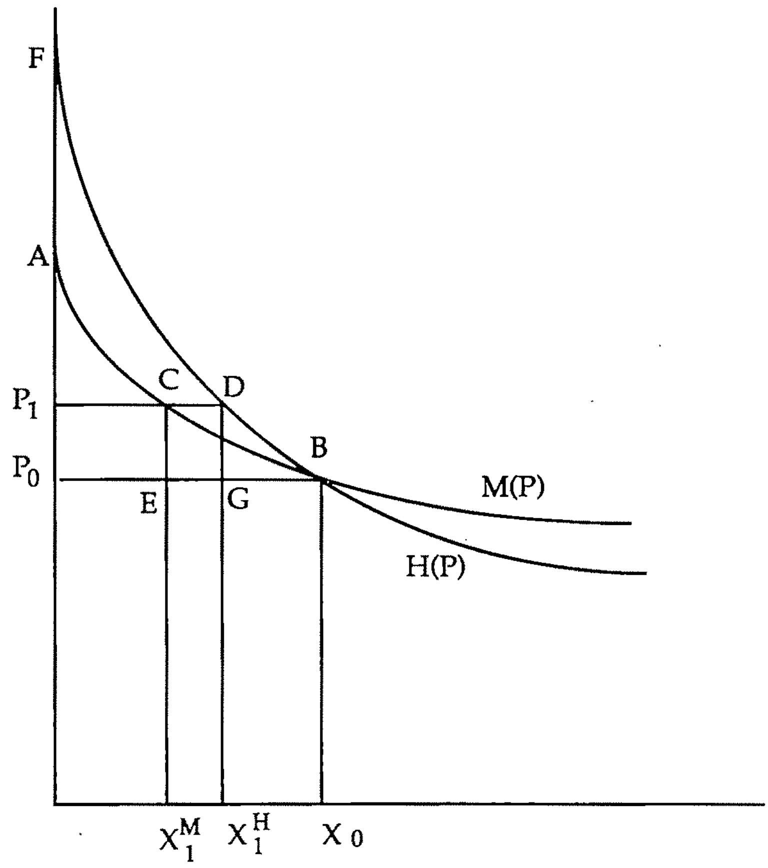

Figure 1. Alternative welfare measures

and variance for a ratio of random variables cannot be expressed analytically in terms of the moments of the two random variables. In fact, the mean and variance for the ratio may not exist (Mood, Graybill, and Boes). For example, the moments of the Marshallian consumer surplus estimator for either the linear or semilog models will not exist unless the price coefficient is restricted away from zero.

In cases where the moments of welfare estimators are known to exist, approximation formulas can be derived based on Taylor's series expansions. For example, approximation formulas for the estimated total Marshallian surplus, $\hat{cs}$, from the linear demand are as follows:

$$\text{(6)}\quad E[\hat{cs}] \simeq \frac{X'^2 + \sigma^2}{-2b} + \frac{X'^2}{-2b}\left[\frac{\text{Var}\beta}{b^2} - \frac{2\text{Cov}(\beta, X)}{X'b}\right],$$

$$\text{(7)}\quad \text{Var}[\hat{cs}] \simeq \frac{X'^2}{b^2}\sigma^2 + \frac{X'^4}{4b^4}\text{Var}\beta - \frac{X'^3}{b^3}\text{Cov}(\beta, X).$$

Equation (6) represents a second-order Taylor's series expansion around $E[X] = X'$, $E[\beta] = b$, while (7) is derived from a first-order Taylor's series expansion around X', b.[2]

That $\hat{cs}$ is a biased estimate of cs^T is a general consequence of $E[R/S] \neq E[R]/E[S]$ for any random variables R and S. As such, bias also exists for point estimates of the other welfare measures in table 1 (except for the linear demand deadweight loss) regardless of whether the X_i or $\hat{X}_i$ are used in the calculations. It has been suggested that the Taylor's series approximation of $E[\hat{cs}]$ in (6) may be useful in correcting for the bias (BHS, Kealy and Bishop). For the linear demand this correction is made by computing and reporting

$$\text{(8)}\quad \hat{cs}^{\text{corrected}} = \hat{cs} - (\hat{X}'^2/-2\beta)[\text{Var}\beta/\beta^2 - 2\text{Cov}(\beta, X)/\hat{X}'\beta],$$

where the second term is the correction factor based on the Taylor's series approximation of $E[\hat{cs}]$ in (6) and the sample estimators $\hat{X}$ and β are substituted for X' and b, respectively, in the $E(\hat{cs})$ approximation.

[2] The formulas in (6) differ from counterparts in the literature (BHS, Kealy and Bishop) apparently because the prior authors expanded $\hat{cs}$ around $E[X^2] = X' + \sigma^2$ rather than $E[X]$ and omitted the covariance term.

However, the accuracy of the second-orde approximation of $E[\hat{cs}]$ has been questioned b G-TAF who suggest that errors from use of th second-order approximation (6) are potentiall large for both the linear and semilog forms. Thei conclusion is based on analysis of a single dat set and a single welfare estimator, Marshallia surplus, and its generality is one focus of th Monte Carlo analysis here. A similar set of con cerns would apply to the approximate varianc formula (7), although they are not addressed i this paper.

Bootstrapping in Applied Welfare Analysis

In the context of applied welfare analysis, th bootstrapping approach evolves in the followin steps (see generally Freedman and Peters):

1. A functional form for consumer demand such as (1) or (2), is chosen. The disturbance u_i are assumed i.i.d. with mean zero. Normalit of the u_i need not be assumed. The model i estimated on the sample data. The estimated pa rameters, α, β, and γ are used to compute welfare estimate, $\hat{w}$.

2. The regression residuals ϵ_i (which are es timates of the true disturbances, u_i) are com puted and used to create a distribution, ϕ. Eac ϵ_i, $i = 1, \ldots, n$, has probability mass $1/n$ i ϕ.[3]

3. New quantities $\{X_1^*, \ldots, X_n^*\}$ are generate by resampling from the residuals, e.g., for th linear model, $X_i^* = \alpha + \beta P_i + \gamma Y_i + \epsilon_i^*$, wher ϵ_i^* is chosen by random draw with replacemen from ϕ.

4. New parameter estimates, $\hat{\theta}^* = \{\alpha^*, \beta^*$ $\gamma^*\}$ and disturbance vector $\xi_i = \{\xi_1, \ldots, \xi_n\}$ ar generated from regressing X^* on P and Y an used to compute a new welfare estimate, $\hat{w}^*$.

5. Steps 3 and 4 are repeated by redrawin some large number, T, of times from ϕ to gen erate an empirical distribution for $\hat{w}^*$. This dis tribution characterizes the statistical uncertaint associated with $\hat{w}$.[4]

Let η denote the distribution of the $\hat{w}^*$ gen erated from the above process. The mean of thi distribution is denoted as $\bar{w}^* = (1/T)\Sigma_t\hat{w}_t^*$. Th

[3] Freedman and Peters (p. 99) suggest inflation of the residual to compensate for the deflation of the residuals in fitting. The suggested inflation factor is employed in the subsequent analysi in this paper.

[4] Variations on this prototype methodology can be employed whe the underlying data is censored or truncated as is common in re reation data sets. See generally Efron (1981a).

difference between $\bar{w}^*$ and the point estimate of welfare provides an estimate, B, of the bias:

$$(9) \qquad B = \bar{w}^* - \hat{w}.$$

That is, in the bootstrap simulation, $\hat{w}$ is the true welfare measure so the average deviation from $\hat{w}$ of the bootstrap-generated $\hat{w}_t^*$ measures the bias. The bootstrap-generated B is compared to Taylor's series estimates of the bias in the next section.

Likewise, Var[$\hat{w}$] can be estimated by computing $E[\hat{w}^{*2}] = (1/T)\Sigma\hat{w}_t^{*2}$, $E[\hat{w}^*] = \bar{w}^*$, and invoking the usual formula:

$$(10) \qquad \mathrm{Var}\,[\hat{w}^*] = E[\hat{w}^{*2}] - (E[\hat{w}^*])^2.$$

A crude confidence interval may be constructed from (10) by assuming that the $\hat{w}$ are distributed normally and computing, for example, $\hat{w} \pm 1.645(\mathrm{Var}[\hat{w}^*])^{1/2}$ to obtain a putative 90% interval for w. However, it is questionable whether the $\hat{w}$ will be distributed normally, particularly in small samples (Hayya, Armstrong, and Gressis; Efron (1981b)). A distribution-free alternative would be $\hat{w} \pm 3.16(\mathrm{Var}[\hat{w}^*])^{1/2}$ based on Chebychev's inequality.

Efron (1981b, 1987), however, has suggested that better confidence intervals can be obtained by more fully utilizing the information contained in η. One possibility is to construct a (1–2δ percent confidence interval for w by deleting the outer δ tails from η.

G-TAF and AFG-T assume that the u_t are distributed normally and generate a vector of disturbances ϵ^* directly from a normal $(0, \hat{\sigma}^2)$ distribution, where $\hat{\sigma}^2$ is the sample variance, rather than from the empirical distribution of the residuals. The merit of this approach is analyzed below using Monte Carlo analysis.[5]

An apparent problem in the AFG-T and G-TAF analyses is that the bootstrap-generated data occasionally produced parameters yielding implausible welfare estimators. Specifically, draws generating absolutely small negative values for β yield very large values of willingness to pay, quite possibly in excess of income. Positive values for β may also be generated, implying negative willingness to pay. Such results are counterintuitive and inconsistent with the underlying economic theory. Yet because these implausible estimators may be very large in absolute value relative to the magnitude of the other bootstrap-generated welfare estimates, they can easily dominate calculations of bias and also cause bootstrap-estimated variances of welfare to be very large. These outcomes most likely reflect an estimator which does not have finite moments (Smith).

The modification proposed and analyzed here eliminates aberrant bootstrap draws using inequality restrictions on the demand function parameters. Specifically, the requirement that willingness to pay must be bounded by zero and total income is imposed:

$$(11) \qquad 0 < \hat{w}_i < Y_i, \text{ for all } i = 1, \ldots, n.$$

These restrictions on the $\hat{w}_i$ translate into inequality restrictions on the demand function parameter vector $\hat{\theta} = \{\alpha, \beta, \gamma\}$. In addition to the restrictions in (11), the modification imposes integrability conditions (BHS) on the demand functions,

$$(12) \qquad X_i < b/c, \text{ for all } i = 1, \ldots, n,$$

for both the linear and semilog functions. These conditions would seem to comprise the least restrictive set of prior information to impose on the analysis. Tighter bounds on the $\hat{w}_i$ would certainly be realistic in many applications. These inequality restrictions might be imposed via quadratic programming at each bootstrap trial (Judge and Takayama), but the distribution theory for this estimator is lacking (Geweke) and the procedure may be inordinately expensive.

An alternative is to impose the restrictions using Bayesian methods wherein restrictions are summarized in the prior density function for θ, $P(\theta)$. The improper prior which imposes the restrictions in (11) and (12) is

$$(13) \qquad P(\theta) = \begin{cases} 1 \text{ if } 0 < w_i < Y_i \text{ and } X_i < b/c,\ i = 1, \ldots, n, \\ 0 \text{ otherwise.}^6 \end{cases}$$

[5] Normality of the u_t is not needed for OLS to be the best linear unbiased estimator, but it is usually invoked to justify classical statistical inference. Bootstrapping provides an alternative to these methods, so it may be unnecessarily restrictive to invoke normality of the u_t in conducting the bootstrap trials.

[6] The compensating variation measures defined in table 1 and used in the Monte Carlo analysis are willingness to accept measures which are not necessarily bounded by income. Therefore, in imposing the inequality constraints, Hicksian equivalent variation measures (which do correspond to willingness to pay in this case) were calculated and employed. A reviewer noted that welfare measurement in the case of corner solutions may complicate the imposition of the constraints. Finally, the measure of income used in the constraints can be an issue since welfare measures may not depend on current income alone.

From Bayes' theorem, this prior density function, when combined with the sample likelihood function $L(\theta|X, P, Y)$, yields a posterior density function,

$$(14) \quad P(\theta|X, P, Y) \propto P(\theta)L(\theta|X, P, Y),$$

where α denotes proportionality. The posterior density is defined only over the parameter space consistent with the restrictions. In the usual Bayesian framework, the regression disturbances ϵ are assumed to be normally distributed, and the likelihood is, consequently, easy to define. However, the posterior density in (14) often cannot be integrated to obtain its moments and Monte Carlo integration (Kloek and van Dijk, Geweke) is used as an alternative. With Monte Carlo integration, a large number of draws of $\hat{\theta}$ are made from the posterior distribution. The mean of these draws is usually used as a point estimate of θ (Geweke). Work applying these methods to welfare estimators has recently been conducted by Adamowicz, Graham-Tomasi, and Fletcher.

The assumption of normal sampling may be an unwarranted feature of the approach (Chalfant and White). An alternative pursued here follows the suggestion of Boos and Monahan to replace the normal distribution likelihood in (14) with the bootstrap estimate of the sampling density of $\hat{\theta}$, to be denoted $\hat{L}(\hat{\theta}|X, P, Y)$:

$$(14') \quad \hat{P}(\theta|X, P, Y) \propto P(\theta)\hat{L}(\hat{\theta}|X, P, Y).$$

Given the prior in (13), the posterior in (14′) is estimated from only those bootstrap trials satisfying the inequality restrictions. The final step in the procedure is to estimate a posterior distribution for w by computing the $\hat{w}^*$ for only those bootstrap trials in which the $\hat{\theta}^*$ satisfy the restrictions in (13).

The bootstrapping approach to incorporating inequality restrictions is quite similar to the Monte Carlo integration methodology described earlier in that the posterior distribution for θ in either case is estimated from only those $\hat{\theta}$ satisfying the restrictions, with nonconforming trials being discarded. The essential difference in the approaches is that bootstrapped data sets, not random number generators, are used to generate the $\hat{\theta}^*$, thus avoiding the need to make possibly erroneous assumptions about the distribution of θ.[7]

[7] It should also be noted that interpretation of the regression model is quite different in Bayesian vs. sampling-theoretic frameworks (Griffiths). For example, whereas θ is treated as nonstochastic in the sampling-theoretic framework, uncertainty about the unknown θ is represented in terms of a probability distribution, e.g., (13), under a Bayesian interpretation.

The Monte Carlo Experiment

The preceeding discussion has raised a number of questions about the practice of applied welfare analysis, including:

(*a*) How significant is the bias of point estimates of welfare, and how accurately can the bootstrap results and/or the second-order approximation of $E[\hat{w}]$ predict this bias? In turn, how is the answer to this question affected by features of the data sample including the sample size, distribution and variance of the u_i, and the share of total consumer surplus relative to the total budget?

(*b*) How is the precision of welfare estimators affected by the parameters of the data sample described above?

(*c*) How do the answers to questions (*a*) and (*b*) vary among the alternative welfare estimators listed in table 1?

(*d*) Is the AFG-T simplification of the bootstrap methodology appropriate?

(*e*) Is the tendency of the bootstrap to yield implausible parameter draws and, in turn, welfare estimates ameliorated by introducing inequality restrictions?

(*f*) Are the bias and precision of welfare estimators significantly affected by the choice of functional form?

The simulation experiment to analyze these issues involved construction of sixteen data sets for both the linear and semilog functional forms. For each function, values were chosen for the parameters a, b, and c. Price (travel cost) and income data (P_i, Y_i) were taken from a Cheasapeake Bay beach survey conducted by Research Triangle Institute for the University of Maryland (BHS). Given values for a, b, c, and the P_i and Y_i, quantity variables, X_i, were constructed for each functional form using equations (1) and (2) by randomly drawing the u_i from an appropriate distribution. The data sets are differentiated based on the following four criteria: (*a*) distribution of the u_i—normal versus uniform, (*b*) magnitude of the error variance—large versus small, (*c*) sample size—25 versus 100 observations, (*d*) magnitude of the welfare measures—large versus small, where large w_i were obtained by increasing the base values of a, b, and c. Thus, each data set was characterized by a unique choice among these four criteria. Exhausting the possible combinations produced the sixteen data sets for each functional form.

For each data set, the true values of welfare were computed for each welfare measure using

the table 1 formulas. Welfare was computed for each individual and then averaged over the sample in accord with standard practice.

Point estimates α, β, and γ, and residuals ϵ_i were obtained for each data set using ordinary least squares (OLS). Given the properties of each data set, the OLS estimators are best linear and unbiased. The estimated parameters and residuals were then used to produce point estimates of welfare following the same process used to compute the true welfare. These estimates correspond to what an applied researcher would obtain. As noted, they are expected to be biased, and no other measures of their reliability would normally be provided. To test the second-order approximation to $E[\hat{w}]$, the adjustment to the $\hat{w}$ given in (8) were also computed for each data set.

The final steps in the simulation experiment involved conducting the bootstrap trials. Three alternative bootstrap procedures were employed on each data set: (*a*) The prototype bootstrap involving resampling from the empirical distribution of residuals, (*b*) The modified bootstrap with inequality restrictions, and (*c*) The AFG-T, G-TAF normal-distribution bootstrap involving sampling the ϵ_i from an $N(0, \hat{\sigma}^2)$ distribution.

One hundred successful bootstrap trials were obtained for each procedure. Thus, more than 100 repetitions were often needed for the bootstrap with Bayesian priors because trials where parameter estimates did not meet the restrictions were omitted. The 100 sets of parameter vectors and welfare estimators obtained for each approach were then used to compute B, Var$[\hat{w}]$, and confidence intervals.

Results

Table 2 contains results from OLS estimation for the first eight data sets for each functional form. The table also contains summary information on the characteristics of these data sets. Data sets 9–16 involved the large welfare measures (criteria 4 above). For brevity, results for these data sets are omitted from the tables, although whenever appropriate mean values are reported for both data sets 1–8 and 9–16. The first four linear and semilog data sets are similar to typical recreation demand data; the R^2's are fairly low, ranging from 0.13–0.53, the *t*-statistics are generally significant, but not extremely large, and consumer surplus constitutes a relatively small part of the consumer's total budget.

The Bias in Welfare Estimates

Table 3 compares estimates of the bias of $E[\hat{cs}]$ from the three alternative bootstrap methods for both the linear and semilog models. The first column in each table reports the actual bias as a percentage of the true welfare measure, i.e.,

[a] Calculation is based on all 16 data sets using equation (16).

$(\hat{cs} - cs^T)/cs^T$. Column 5 reports the percentage bias estimated by the Taylor's series adjustment factor in (8), i.e., $(\hat{cs} - cs^{corrected})/cs^T$. Likewise, columns 2–4 report the estimated percentage biases from the three bootstrap methods. These biases are computed as the difference between the average cs^* from the bootstrap trials and the point estimate, $\hat{cs}$, and are reported as a percentage of cs^T.

Both the prototype and normal-distribution bootstrap methods in some instances predict very large biases. In general, the bootstrap modified by inequality restrictions is free from these aberrations. In considering these results, note that over a large number of trials the various bootstrap methods must yield an accurate estimate of the bias in their respective simulation worlds. However, use of the bootstrap estimates of bias to "correct" for the bias in a single data sample is another matter. Table 3 suggests that such a correction is probably inappropriate. The table reports the root mean square percentage error (*RMSPE*) from each method of approximating the actual bias from the data sample for each functional form, i.e.,

$$(15)\quad \text{RMSPE} = \sqrt{(1/16)\Sigma(\text{Actual Bias} - \text{Predicted Bias})^2}.$$

These numbers should be compared to treating the $\hat{w}$ as unbiased, i.e., substituting zero into (15) in place of the predicted bias. These numbers are reported in the actual bias column of the *RMSPE* rows in table 3. The modified bootstrap on average predicted the magnitude of bias roughly as well as the default assumption of no bias, but both the prototype and normal-distribution bootstraps performed much worse, supporting the conclusion that bootstrap estimates of bias should probably not be used to adjust point estimates of welfare. Interestingly, the second-order adjustment (column 5) did not fare much better in predicting the magnitude of the bias; the *RMSPE* from the use of $cs^{corrected}$ is only slightly smaller than the *RMSPE* from the zero predicted bias default in the linear model.

Another interesting question regarding the bias of welfare is whether the relative magnitude of the bias differs among different welfare measures or the use of Hicksian rather than Marshallian measures. Table 4 reports t-statistics for tests of whether the bias is significantly different from zero for each of the six welfare measures outlined in table 1.[8] All calculations are based on results from the modified bootstrap.

The bias was significant at the 95% level for the linear model in twenty-six of ninety-six in-

[8] The t-statistics are computed as the ratio of the bias to its standard error, where the standard error is calculated as the standard deviation of the $\hat{w}^*$ from the bootstrap trials divided by $(T)^{1/2}$.

[a] Asterisk indicates significance of the bias at the 95% confidence level.

stances, including the large *cs* data sets not reported in table 4. Not surprisingly, the biases were more frequently significant when the error variances were large (18 of the 26 cases) and when the sample sizes were small (19 of the 26 cases).

Data sets 9–16 wherein *cs* was a large fraction of income yielded somewhat more (15/26) of the significant biases than did data sets 1–8. Also notable is that the small price change welfare estimates were less susceptible to bias than were the total surplus or deadweight loss measures. Results for the semilog model were less clear. Across the sixteen data sets, roughly the same number of biases were significant as in the linear model, but just over half of the cases with significant biases also had high variances (17 of 31) or small samples (16 of 31). Once again, the bulk of the significant biases (23/31) came from data sets 9–16.

These results suggest that more and better data are important in reducing estimation bias. However, the number of significant biases discerned for data sets with 100 observations suggests that bias may be an important consideration even for relatively large samples.

The results also indicate that the bias can be either positive or negative with 33/96 instances yielding negative biases for both the linear and semilog models. This result contradicts the conclusion of BHS that Marshallian surplus estimates are biased upward.[9]

The Precision of Welfare Estimates

To examine the relative performance of the alternative bootstrap methods in calculating the precision of welfare estimates, coefficients of variation (CV) were computed for each bootstrap method for the total consumer surplus estimator. The CV is the standard deviation of the bootstrap distribution of the $\hat{w}^*$, divided by the mean, $\bar{w}^*$, of the distribution. Hence, large CVs imply imprecise point estimates and correspond roughly to large confidence intervals. CVs are used rather than confidence intervals because of their more compact representation.

The results, shown in table 5, are strikingly consistent for both the linear and semilog models. The prototype bootstrap and the AFG-T normal bootstrap produce some extremely large CVs that are eliminated when the modified bootstrap is used. For example, the omission of a single bootstrap trial in the first linear model data set

[9] The BHS conclusion was based on comparing the expected value of their expansion of $\hat{cs}$ to $E[cs^T]$ in (5). The discrepancy may be due to the truncation of the Taylor's series or BHS's alternative expansion procedure (see note 2 above).

Table 5. Coefficients of Variation for Total Consumer Surplus from the Alternative Bootstrap Methods

Data Set	Prototype	Modified[a]	Normal	Normal Modified
Linear model

7	0.12	0.12 (100)	0.12	0.12
8	0.39	0.39 (100)	0.45	0.45
Mean 1–8	0.54	0.54	4.70	1.02
Mean 9–16	4.81	0.26	3.03	0.28

[a] The number of trials used in the modified bootstrap method is reported in parenthesis.

results in a drop in the coefficient of variation from 27.98 to 0.97. Other cases of large improvements in the variance estimates also occur. These improvements are particularly likely to occur when the error variances are large or the number of observations is small. Use of the modified bootstrap induces a six-to-tenfold reduction in the reported variance of $\hat{cs}$. The large variances generated by the unrestricted models undoubtedly reflects estimators without finite moments.

To determine how much of the large variance estimates in the AFG-T normal bootstrap were due to the assumption of normal errors versus the inclusion of bootstrap trials which did not conform to the inequality restrictions in (11) and (12), the experiment was repeated employing both normal errors and the inequality restrictions. As reported in column 4 of table 5, with the exclusion of the aberrant bootstrap trials, sampling from a normal distribution generated results similar to those generated by sampling from the empirical distribution, an average CV of 0.55 from the normal vs. 0.40 from the empirical distribution for the linear model and 0.65 vs. 0.40 for the semilog.

Even in cases where the true errors were uniformly distributed, sampling from a normal distribution did not appear to significantly alter the findings. These results suggest that a normal distribution can be used without introducing substantial errors.

To examine the relative sizes of the coefficients of variation across alternative welfare estimators, table 6 reports CVs from the modified bootstrap for each of the six welfare estimators in table 1. The results are again quite similar for the linear and semilog models and several notable patterns emerge. First, even though the Hicksian measures are computed from estimates of Marshallian demand functions, rely on income coefficients as well as price coefficients and have more complex formulas, the CVs for the Hicksian and Marshallian measures are quite similar. Even data sets 9–16, which produced noticeably different Hicksian and Marshallian measures, yielded similar coefficients of variation.

Second, the total consumer surplus and total compensating variation measures were generally estimated less precisely than the other measures, but the most significant difference was in the precision of estimation of small price change consumer surplus. This result can be explained by noting the portion of each welfare estimate that relies on the precision of the regression estimates. For example, total consumer surplus is the area under the entire demand curve for a given price and, as a result, the measure is likely to be very susceptible to slight changes in the price coefficient. In contrast, the small price change consumer surplus measure contains a large portion which is nonstochastic, the area $(P1 - P0)X1$. The deadweight loss measure is computed by subtracting the nonstochastic component from the small price change consumer surplus, and as such, it shares the total consumer surplus's reliance on the precision of the price coefficient estimate.

Finally, the CVs reported in table 6 provide a rough idea of the magnitude of the confidence intervals around the point estimates of welfare. If plus or minus two standard deviations is used as a rough approximation to 95% confidence intervals, then the average confidence interval around *cs* for both the linear and semilog models is approximately plus or minus 80%, with a range from 12% to 506%. Imprecision is particularly acute for those data sets that are most similar to observed cross-sectional data. For example, the confidence intervals for the first four data sets

Mean 9–16	0.26	0.09	0.22	0.31	0.10	0.23

Note: All estimates are based on the modified bootstrap method.

average about plus or minus 220% and 185% of the *cs* for the linear and semilog models, respectively. The $n = 25$ data sets also generate significantly larger confidence bounds—plus or minus 162% and 192% for the linear and semilog models compared to 84% and 26% for the $n = 100$ data sets. Once again, there appear to be large returns to generating more observations and getting better model fits.

It is also illuminating to compare the standard errors of the $\hat{cs}$ to Willig's bounds on the difference between the Marshallian and Hicksian total welfare estimates (Willig). The ratio of two standard deviations of $\hat{cs}$ to the Willig bounds were computed for each of the sixteen point estimates of *cs* for the semilog model. The average of these ratios across the data sets is about 774. The first 8 data sets, where the difference between the Marshallian and Hicksian measures was very small, yielded, as expected, a much larger average ratio of about 1,520. However, even when considering only the second 8 data sets, where the differences between the Marshallian and Hicksian measures was much larger, the average ratio was 14.05. These results suggest that there are far higher returns from improving the precision of our estimates than from worrying about calculating "exact" measures of welfare. There appears to be a great deal of inexactness when it comes to estimating our "exact" measures.

It is important to emphasize that confidence intervals computed from the bootstrap distribution described earlier will reflect any asymmetries in the small sample distribution of the $\hat{w}$ (Efron 1981b, 1987) and, hence, represent a preferred alternative to crude intervals generated from estimates of the standard error. For example, with the linear model and data set no. 1 the crude 90% confidence interval is $\hat{cs} \in [0, 726.5]$, while the estimated interval derived from the bootstrap distribution with 1,000 trials and Efron's percentile method is $\hat{cs} \in [212.4, 806.1]$. The 90% Bayesian highest posterior density interval (Griffiths) is $\hat{cs} \in [160.4, 585.9]$. Bayesian confidence intervals, it should be noted, are interpreted differently than sampling-theoretic intervals (Griffiths).

A final issue is the appropriate number of bootstrap trials to conduct. A criterion proposed by Kloek and van Dijk for choosing the number of trials in Monte Carlo integration is also pertinent to the bootstrapping scenario. Based on the central limit theorem the mean values from a random sample (e.g., a sample generated from bootstrap trials or Monte Carlo integration) are

approximately normally distributed for sufficiently large n with standard error for the mean equal to the standard error of the sample [see eq. (10)] divided by $n^{1/2}$. Thus, precision of estimation of the mean, say $\bar{w}^*$, can be improved by increasing (in our case) the number of bootstrap trials. From, an estimate of the standard error of the sample and a criterion for precision, it is possible to solve for the approximate number of trials needed to obtain the desired precision.

The precision criterion used here is that a 95% confidence interval around $\bar{w}^*$ should be no wider than $\pm .1\bar{w}^*$, i.e.,

$$\bar{w}^* + 1.96SE[\bar{w}^*] < 1.1\bar{w}^*, \tag{16}$$

where $SE[\bar{w}^*] = (\text{Var}[\hat{w}^*]/n)^{1/2}$ and $\text{Var}[\hat{w}^*]$ is computed from (10). Solving (16) for n provides the estimated minimum number of trials needed to achieve the desired precision.

Applying this criterion to our data sets for the modified bootstrap indicated that 100 successful trials were insufficient for six of the thirty-two data sets: linear #'s 1, 2, and 4 and semilog #'s 2, 4, and 10. These models were re-evaluated using the number of bootstrap trials indicated from solution of (16). The results for bias and coefficients of variation from the expanded trials are reported in table 7. Results from the original 100 successful trials are also provided for comparison. Quite substantial changes in coefficient of variation and bias were found for the linear models, reflecting the imprecision of the results based on 100 trials for these models. Conversely, results did not change much for the three semilog models.

Table 7. Coefficients of Variation and Biases for Total Consumer Surplus from the Modified Bootstrap Using the 10% Accuracy Rule

		Coefficients of Variation		% Biases	
Data Set	Trials[a]	100 Trials[b]	10% Rule	100 Trials[b]	10% Rule
Linear model					
1	361	0.97	0.63	39	22
2	659	1.31	2.38	46	53
4	983	1.60	3.33	44	53
Semilog model					
2	139	0.79	0.66	22	19
4	2459	2.53	2.47	106	93
10	177	0.68	0.60	25	19

[a] This column reports the number of trials satisfying the inequality restrictions undertaken as determined by the accuracy rule discussed in the text.
[b] These coefficients of variation and percentage biases are reproduced from tables 5 and 3, respectively.

Conclusions and Recommendations

Bootstrapping techniques can facilitate applied welfare analysis by enabling researchers to discern whether welfare estimators are likely to exhibit significant bias and to construct standard errors or confidence intervals without appealing to asymptotic properties or making assumptions about underlying error distributions. The simulation results demonstrate the marked improvements possible through imposition of innocuous, theoretically based inequality restrictions on the bootstrap-generated parameters.

Bias in the various welfare estimators was often significant, particularly in the cases most relevant for recreation demand analysts. Although the bootstrap is able to isolate these biases, neither the bootstrap nor the Taylor's series correction were particularly successful on average in predicting the biases from individual data sets. However, bootstraps without the inequality restrictions were much worse at predicting bias. This suggests that the discrepancy between the second-order approximation and bootstrap mean noted by Graham-Tomasi, Adamowicz and Fletcher is probably due to the unmodified bootstrap's poor performance rather than the truncation bias of the second-order approximation, as G-TAF conclude.

The results also demonstrate that welfare measures can be estimated quite imprecisely, especially for data samples typical of applied recreation analysis. Standard errors for the total Hicksian and Marshallian measures in these cases were, on average, of the same magnitude as the point estimate, and the associated confidence intervals were much larger than either the Willig bounds or the biases.

The coefficients of variation and bias from the modified bootstrap for the linear and semilog models were very similar. This suggests that the effect of functional form on variance and bias may be alleviated by imposing inequality constraints. Thus, choice of functional form (Kling) can be based on other factors, such as goodness of fit, rather than concerns about alternative functions' tendencies to generate welfare estimators with inherently larger biases or variances.

Finally, and perhaps most instructively, the simulation results indicate that both the biases and the variances of welfare estimators can be

reduced, sometimes dramatically, with more data and better fits of the models. There may be higher returns to collecting more and better data than from worrying about theoretical discrepancies between various measures.

Signals or Noise? Explaining the Variation in Recreation Benefit Estimates

V. Kerry Smith and Yoshiaki Kaoru

This paper uses meta analysis to summarize the benefit estimates derived from travel cost recreation demand models. After reviewing approximately 200 published and unpublished studies prepared from 1970 to 1986, 77 were found to report either consumer surplus estimates or sufficient information to derive them. Using these estimates of the consumer surplus per unit of use from each study, it was possible to evaluate the influence of variables describing the site characteristics, the activities undertaken at each site, the behavioral assumptions, and the specification decisions. The findings provide clear support for using econometric methods to summarize results from diverse empirical studies. They highlight the important research issues in model development and offer a consistency check to the procedures used in benefit transfer analyses for policy evaluations.

Key words: consumer surplus, meta analysis, recreation demand.

This paper proposes a new method for taking stock of current estimates of the benefits users derive from environmental resources: an econometric review of the literature. This approach is applied to empirical studies using the travel cost method to estimate the demand for specific recreation sites, but it has general relevance for gauging what has been learned by empirical research in many other areas of economics.[1]

The research landscape for benefit estimatio has changed dramatically since Freeman wrot his influential overview of the field in 197S Freeman's book responded to a gap in the li erature on benefit estimation. There had bee "substantial research effort devoted to deve oping a rigorous and unambiguous definition an measure of changes in welfare at the theoretic level . . ." but "relatively little concern fc translating the theoretical concepts and defin tions into usable, operational empirical tecl niques" (Freeman, p. 15). This situation ha changed, especially in the United States. Of th 77 travel cost recreation demand studies ana lyzed in this paper, 61 were prepared since 198C Mitchell and Carson identified over 120 contir gent valuation studies, most completed afte 1980. Of the 35 hedonic property value studie considering the effects of air pollution, 30 be came available after 1980. Certainly the ir creased role given to benefit-cost analyses fc evaluating environmental policies in Executiv Order 12291 (issued in February 1981) has cor tributed to the dramatic expansion in this litel ature [Smith 1984 and Office of Policy Analy sis, U.S. Environmental Protection Agenc (EPA) for evaluations]. Nonetheless, the avai able benefit estimates fall short of what is neede for an increasing array of policy related activi

This research was partially supported through the U.S. Environmental Protection Agency Cooperative Agreement No. CR812564.

A large number of individuals contributed to this effort by providing the source materials for both published and unpublished papers. Since the authors wrote to all the individuals whom they could identify as active researchers in recreation economics, and all chairs of Departments of Agricultural Economics and of Economics, they cannot identify them individually. Thanks go to Michael Hanemann for calling the authors' attention to the meta-analysis literature outside economics and to John Braden, Jerry Carlson, Peter Caulkins, Bill Desvousges, Ted McConnell, and three anonymous referees for exceptionally careful and constructive comments on earlier drafts of this paper.

[1] Hedges and Olkin credit Glass with the first use of meta-analysis in educational and psychological research. There are important differences in the use of these methods for applications in these disciplines, as well as for medical research, in comparison with economics. All of the former have involved controlled experiments, where the statistical analysis can be treated as aggregating independent observations from each study's sample of experimental findings (see Cordray).

ties (Ward and Loomis; Naughton, Parsons, and Desvousges).

Indeed, the practice of adjusting the results from one or more existing studies for a specific type of environmental resource and using them to value changes in another resource is commonplace in policy analysis. Labeled "Benefits Transfer," this process usually involves: (*a*) adjusting or transferring an estimated model (or set of per unit benefit estimates) from the situation where it was developed to the new application; and (*b*) developing an aggregate estimate for the relevant population from per unit estimates and other assumptions. While judgment is important in both steps, it has been the principal basis for the first step. Many of the published sources used for benefit estimates in policy analysis were not designed to provide measures of the benefits for a change in the quantity or quality of a resource. Rather, they were developed to introduce a new model, test a hypothesis, evaluate the implications of specific assumptions, or illustrate a new estimator. Consequently, they must be adapted for benefit measurement. The nature of these modifications depends upon both the benefit estimation task and the information reported in the original sources.

Our findings show a systematic relationship between the estimates and the features of the empirical models. Both the type of recreation site involved and the assumptions made in developing the empirical models are important in explaining the results. The variables used to describe models are classified according to whether they attempted to reflect specific theoretical issues associated with individuals' recreation decisions or analysts' judgments needed to estimate a model (e.g., selecting a functional form for the demand model or making assumptions to compensate for inadequate data). Ideally, the latter variables would not be important determinants of the variation in benefit estimates, but the findings here suggest that they are.

The specific factors found to be significant determinants of the real consumer surplus per unit of use have direct implications for research on households' recreation decision making, for further uses of the travel cost demand model, and for the practices used in transferring benefit estimates derived from this class of models to new applications. These implications are explored in the last section of the paper, after developing the background, describing the data set and methodology, and presenting the results.

Statistical Methods for Synthesizing Research

The use of statistical methods to develop a research synthesis has a long history. Termed meta analysis, most of these applications have involved controlled experiments in psychology, education, or the health sciences. They have focused on consistently aggregating the results from different controlled experiments. The methods are motivated by the desire to avoid the subjective nature of most research reviews. Conventional reviews of empirical literature usually summarize the presence or absence of statistically significant effects and, in some cases, compare the size of estimated effects. While many of these studies have attempted to draw some bottom line conclusions about what is known (as Light and Pillemer observed), these types of appraisals often violate simple statistical principles in distilling an admittedly complex array of work. Moreover, to develop this type of summary, the reviewer usually must adapt the multiple (and often complex) features of the studies to fit some comparable format in order to propose a consensus judgment.

Because empirical research in economics is usually not based on experimental data and may well report multiple models applied to a single data base, our proposed methodology is different from that used in most meta analyses (Cordray). It must reflect both the modeling judgments (made because controlled experiments are usually impossible) and the interdependent panel nature of any sample of research results. Fortunately, both issues can be addressed with existing econometric methods.

Moreover, the rationale for using an econometric framework for synthesizing the benefit estimates for environmental resources is more general. Empirical models are combinations of prior theory and the analyst's judgment. That judgment combines at least four elements: the problem or issue the empirical model seeks to address (e.g., test a hypothesis or estimate a specific parameter or quantity); the economic theory of behavior relevant to the problem; the data available to estimate the model; and the learning that accompanies evaluating the joint effects of functional specification, variable construction, and the results from prior model formulations in relationship to the existing literature.

The last of these, sometimes referred to as specification searches or data mining, has been

widely criticized in the recent econometric literature. However, by viewing models as approximations, there is further motivation for using statistical summaries of the results from existing models to evaluate the importance of such compromises for the findings.

A Simple Model of Recreation Demand

The travel cost recreation demand model can be described as a derived demand for a recreation site that contributes to each individual's production of a recreational activity providing utility (Deyak and Smith or Bockstael and McConnell 1981, 1983). This framework helps to describe the components of modeling decisions that may explain the variation in consumer surplus estimates across travel cost demand studies.

Consider a simple utility function specified in terms of the activities a person wants to consume, S_i's, as in equation (1).

$$(1) \qquad U = U(S_1, S_2, \ldots, S_k).$$

Each S_i is assumed to be produced by combining market goods, x_{ji}'s; time, t_i; and nonmarketed commodities, y_{ki}'s, as in equation (2). Of course, some activities may not use some inputs.

$$(2) \qquad S_i = f_i(x_{1i}, \ldots, x_{ni}, t_i, y_{1i}, \ldots, y_{mi}),$$

where $x_{1i}, \ldots, x_{ni}$ are the amounts of the n marketed commodities, t_i is the amount of an individual's time, and $y_{1i}, \ldots, y_{mi}$ are the amounts of the nonmarketed commodities, all used in the production of S_i. In recreation applications, these are the services of the recreation sites used by each individual. Budget and time constraints must be added to formally derive the implications of this model for travel cost demand models.

The specification of these demand functions will follow from the assumptions incorporated in these constraints. For example, if the analyst assumes the length of time spent on site during each trip is constant, site entrance fees are negligible, and any free time could be spent working at a predefined wage, then the quantity demanded for a site can be readily measured by the number of trips to the site (v). Moreover, the implicit price of a trip becomes the sum of vehicle-related travel costs and the opportunity costs of travel time (evaluated at the wage rate). This is represented as P.

If the amount of time each individual has available for work or leisure is fixed for the p riod of analysis and known, Becker's full i come (I) becomes the relevant income measu in this demand function. Substitute sites' trav costs (i.e., vehicle and time) and the prices other commodities relevant to these decisions ca also be justified as arguments (P_s). Most ec nomic models assume individuals share con mon behavioral objectives and usually mainta that heterogeneity in people's responses aris from taste differences. These effects are repr sented with demographic characteristics (d Thus, at a general level, the site demand fun tion would be given by equation (3)

$$(3) \qquad v = g(P, P_s, I, d).$$

In most applications, features of this function c transformations of it are the focus of the ana ysis.

In developing an econometric review of thes studies, the feature(s) of $g(.)$ that will be the fc cus of the summary must be identified. If a studies adopted a common specification for th demand function, one might use specific paran eters and the meta-analysis would be similar t the varying parameter models used to estimat the effects of quality changes on site demanc (Vaughan and Russell or Smith and Desvousge [1985]). Even without a common form, th marginal effects or the elasticities could be th focus of an econometric summary.

To evaluate which measure might be best, w need a model of the process of developing ir dividual models (Hendry). However, in pract cal terms, statistical summaries depend on th use of the results and the amount of informatio reported with each study.

Because an important objective of this revie is to evaluate the properties of benefit estimate derived from these models, we selected the cor sumer surplus (CS) per unit of use (v). This se lection attempts to adjust for the accessibility c recreation sites to users by averaging the cor sumer surplus over the use relevant to the tim horizon of the model. It is also consistent wit evaluating the transferability of existing mode because the focus of these efforts is often to de velop unit benefit estimates that can be applie to new situations. Unfortunately, convention theory does not offer clear guidance on the ex pected properties of this measure. This is easil seen by describing it in terms of the deman function in (3). CS/v can be defined formall by

$$CS/v = L(P_o, P_c, P_s, I, d) = \int_{P_o}^{P_c} [g(p, P_s, I, d)/g(P_o, P_s, I, d)]dp, \tag{4}$$

where P_o is the current price and P_c is the choke price.

The estimates of consumer surplus from the literature are generally for specific sites or derived from regional travel cost models hypothesized to describe sets of sites in the same geographic region. To estimate CS/v requires some specification of the variables hypothesized to influence $L(.)$. In many cases, the estimates were provided in the studies. Where they were not provided, information reported in each study was used to estimate the consumer surplus per unit that was representative for a typical user of the site. Developing a model for how CS/v would vary across studies requires recognition that it may vary for different types of recreation sites because their demand functions would be different. Depending on the role of other variables influencing these demands, the type of site could also be a factor affecting $L(.)$. Equally important, different studies have adopted different assumptions about the household's choice problem. These differences alter how the own price of a site or of substitutes is measured. A priori we do not know which characterization is best. Because these maintained assumptions serve as prior restrictions in the estimated models, the estimates of CS/v likely will be affected. Finally, the data available will often constrain the modeling features and must be reflected as well.

For travel cost demand studies, these factors can be classified into five types of decisions: (*a*) specifying the types of recreation sites; (*b*) defining a recreation site, its usage, and the site quality; (*c*) modeling the opportunity cost of time; (*d*) describing the role of substitute sites in producing the recreation service flows; (*e*) linking the specification of the demand model to an underlying behavioral model.

Types of recreation sites. The household production framework recognizes site demand as a derived demand. Thus, both the types of site services and the types of activities undertaken must be considered. In an early attempt to classify recreation sites, Clawson and Knetsch identified three categories—user-oriented, intermediate, and resource-based. User-oriented sites included city and county parks, golf courses, tennis courts, swimming pools, playgrounds, etc. Intermediate sites were federal and state reservoirs and parks that provide hiking, camping, fishing, boating, and hunting. Resource-based sites had special physical characteristics and were mainly national sites. Their unique attributes cause recreationists to perceive recreation at these sites as distinctive from the same activities undertaken elsewhere.

The Clawson/Knetsch perspective is adopted here, but cursory site descriptions in many of the studies force our categorization to be crude. A site is allowed to belong to more than one category. A site with a lake simultaneously may be a national park with wilderness significance. To reflect the differences in users' activities at each site, we identified from each study's description the primary activities a site supported and used this information to specify qualitative variables for each study's demand function.

These activity variables may also capture the influence of the model screening associated with pretesting. An analyst's evaluation of a model can involve comparing its consumer surplus estimate with results from the past literature to gauge the model's plausibility. Because most of the commonly accepted estimates of per-unit values have been for recreational activities rather than recreation sites, variables describing activities undertaken at sites may be proxies for the informal screening rules used in model selection. Examples of the activity-based sources for recreation value estimates include the Water Resource Council estimates of unit day values, the Sorg-Loomis review for the Forest Service RPA process, and (most recently) the Walsh, Johnson, and McKean update of the Sorg-Loomis summary of the benefits per day of specified recreational activities.

Identifying a recreation site and measuring its use. The early travel cost literature treated sites as well-defined entities. However, site definition can be hampered by three factors: (*a*) large resources, such as national forests or estuaries, where the areas do not have uniform characteristics and there are multiple entry points, but no obvious basis for defining subsets of the area for separate analysis; (*b*) large numbers of similar resources in close proximity to one another, such as lakes or ski sites, where each lake is a close substitute for the others and is about the same distance from the bulk of potential users; and (*c*) data constraints that limit our ability to isolate

the resource providing the service, such as deep-sea fishing.

In response to these difficulties, several studies pooled data across sites, arguing that their parameters were approximately constant (Sutherland [1982a]) or that site characteristics could be explicitly incorporated into the model (Vaughan and Russell, Smith and Desvousges 1985).

The variables used to measure an individual's quantity demanded of a site's services are also important in distinguishing the available models. This specification is another example of a decision where an a priori selection of a "best" measure is not always apparent. In particular, price measurement must be coordinated with quantity measurement. Some quantity measures can imply nonlinearities in the individual's budget constraint. Defining use typically involves two considerations—the treatment of on-site time per trip and the time horizon for decision making. From the perspective of a season, if y_{kl} in equation (2) represents the use of recreation site k, we might ask if site use is measured as total time at the site or if trips and time-on-site per trip should be distinguished. For many activities, the "production process" for a day of recreation is comparable to what would be involved in a longer stay. Longer trips allow more of the activity (service flow) to be produced. For other activities, this assumption is not reasonable. Price per unit of use will have both fixed and variable components if use-per-trip is not held constant. Thus, the measure selected for quantity will be important to the existence of a conventional Marshallian demand function.[2] Based on these arguments, we define variables that describe the measurement of use (i.e., days versus trips) and the treatment of on-site-time in the models.

Opportunity cost of time. There are a variety of potential specifications for the constraints to household utility maximization—technology, income, and time constraints. The full income concept, following Becker's original usage, links time and monetary constraints by defining income in terms of earnings and other sources of income. Time is assumed to be freely substituted in any use, so all uses of time have th same opportunity costs (the wage rate). An a ternative specification allows for different op portunity costs, using the wage rates for par time work (Bockstael, Strand, and Hanemann Yet another possibility specifies different tim constraints and maintains that not all types o time can be substituted (Smith, Desvousges, an McGivney).

With detailed information on the time cor straints, wage rates, and job opportunities fo individuals, these models could be tested. Ur fortunately, because there are data limitation the literature offers a selection of approxima tions. Because wage rates are often unknow they must be estimated.

The time horizon for decision making is es pecially relevant to comparisons of recreatio models developed using a random utility (RUM framework (e.g., Bockstael, Hanemann, an Kling or Morey, Rowe, and Shaw). RUM mode seek to explain decisions on single trips, as each decision was independent of prior dec sions. Opportunity costs then must be treate differently because the compressed decision ho rizon may limit the choice set.

Measures of site usage and individual time a location decisions are exceptionally limited. Thu analysts have usually proposed informal rule such as maintaining that opportunity costs ar between one-fourth and one-half the level of th wage rate (Cesario and Knetsch). The prese analysis employs variables that describe how pa studies measured the wage rate and how the described the opportunity cost of travel time.

The treatment of substitute sites. There is li tle to debate about the relevance of substitut prices for modeling the demand for any com modity, including recreation sites. As a rul however, microlevel recreation surveys includ information on the respondents' judgments abo their "next best alternative" without determi ing what sites are actually available and how po tential users perceive alternative sites. Furthe more, collinearity between price measures ca yield the appearance of a small role for subst tute prices (Rosenthal 1985, 1987). For the mo part, past treatments of substitutes can be groupe into three alternatives: (*a*) excluding substitute (the majority of the work); (*b*) formulating a bitrary indexes of existence of substitutes usin a diverse array of specifications (each with littl connection to micro theory); and (*c*) includin a selection of substitute prices. These altern

[2] This problem is analogous to the issues raised in modeling the demand for electricity in the presence of declining block rates (see Taylor for an early discussion) or in the more recent analyses of hedonic models' ability to recover estimates of the willingness-to-pay functions for nonmarketed resources. See Bartik and Smith.

tives are captured in variables describing the treatment of substitutes for the present analysis.

The behavioral framework and the empirical model. Any model specification introduces implicit restrictions that affect how any sample of actual choices is described. Economists working with recreation demand modeling are beginning to question how these implicit restrictions should be selected. For example, Kealy and Bishop; Bockstael, Hanemann, and Strand; and other authors argue that these specifications should follow from a well-defined behavioral model, based on a specific functional specification for either the direct or the indirect utility function. A contrasting view might suggest that, because information is incomplete, starting with a "reduced-form" approximation is just as effective as using a complete behavioral description.

An examination of existing studies cannot answer this question, because the truth is not known. Nonetheless, an evaluation of the influence of the demand specification on the consumer surplus estimates indicates whether an answer is important. To this end, the variables used to describe each set of estimates were grouped into two classes—one reflecting economically plausible maintained hypotheses and a second reflecting ad hoc adjustments where either the economic theory does not provide guidance or limitations in the available data require assumptions. By testing whether the second set of variables accounts for a significant share of the variation in the consumer surplus estimates across studies, the importance of ad hoc modeling decisions can be gauged.

Data and Empirical Model

The analysis is based on a review of published articles in a wide array of journals that included travel cost demand models, government reports, and unpublished papers, as well as masters' and Ph.D. theses from 1970–86. The studies were identified by surveying all issues of the relevant journals; by contacting economists who have developed travel cost demand models, government agencies (e.g., the Fish and Wildlife Service, Office of Policy Analysis in the Department of Interior, Forest Service Regional Offices, and others) and the chairpersons of departments of agricultural economics and economics for unpublished papers and graduate students' masters and Ph.D. essays; and by reviewing the University of Michigan microfilm listings for the abstracted Ph.D. dissertations in resource economics. To the extent possible, double entries for unpublished Ph.D. theses, and subsequently published articles were avoided.

Approximately 200 studies were reviewed to determine if they had empirical estimates for travel cost recreation demand models and provided sufficient information to estimate the Marshallian consumer surplus per unit of use. The results described here relate to 77 studies that either reported benefit estimates or provided sufficient information to derive them. The appendix lists the studies and the range of consumer surplus estimates in real terms for those with sufficient information to be included in the final empirical models (columns 6, 7, and 8 in table 2). Using all 77 studies, there would be 734 observations for our analysis. However, as discussed below, the information is not complete on all variables. Moreover, several studies are responsible for multiple observations because they reported alternative results due to different functional forms, maintained assumptions, estimators, or definition for the recreation sites. Consequently, the sample resembles a panel data set, and this feature must be reflected in the analysis.

The basic empirical hypothesis is that the variation in benefit estimates arises from differences in the theory underlying these demand analyses together with practical implementation issues. The variables used to explain variation in the estimates of benefits can be classified according to (*a*) the assumptions inherent in the behavioral model underlying the travel cost framework, including the measures for quantity and own price and the treatment of substitutes (designated here by a vector of variables, X_B); (*b*) the specifications of the estimated demand function (designated by a vector of variables, X_D); and (*c*) the econometric estimator (designated by a vector, X_E). Equation (4) defined consumer surplus per unit of use for a given recreation site. As observed earlier, in formulating hypotheses concerning the effects of each class of variables on variations in the estimates of CS/v, it is important to recognize that the features of each recreation site (X_S) and the recreational activities undertaken (X_A) should influence the true value for consumer surplus per unit. Moreover, differences in the assumptions made for the variables in $L(.)$ will contribute to variations in estimates of CS/v. If differences in these specifications for other economic and demographic variables are not important, then the true surplus

might be hypothesized as a function of variations in X_S and X_A as in equation (5) where the subscript i is used to designate each estimate.

$$(5) \qquad (CS/v)_{Ti} = \alpha_0 + \alpha_s X_{Si} + \alpha_A X_{Ai}.$$

Only the semilog demand specification satisfies this condition. If b designates the absolute value of the price coefficient, then $1/b$ is often used as a measure of the Marshallian consumer surplus per unit of use and would be the estimator of CS/v. The measure of use would depend on the definition of the quantity variable used for the model.[3]

If economic and demographic characteristics of the samples are greatly different for the same type of site across studies, then we would expect α_0 to vary with those differences. $(CS/v)_T$ is measured per unit of use to reflect differences in the conditions of access across studies. This formulation implicitly assumes the average consumer surplus per unit of use should be comparable (for the same types of resources, uses, and individuals) when the conditions of access are comparable.

Estimates of $(CS/v)_T$ will be functions of demand parameter estimates, as well as the variables determining individual demand. Because these estimated parameters are functions of the true values of the parameters, it is reasonable to hypothesize that the estimated consumer surplus per unit of use, $(CS/v)_E$ is some function of $(CS/v)_T$. Our proposal for summarizing empirical work implicitly maintains that more factors are involved—the variables describing each study's maintained behavioral assumptions (X_B), as well as each analyst's judgments (X_D and X_E). Equation (6) hypothesizes that these effects are additive influences to the true value and therefore would be reflected in the bias in any estimator for $(CS/v)_T$.

$$(6) \qquad (CS/v)_{Ei} = \beta(CS/v)_{Ti} + \gamma Z_i + \epsilon_i,$$

where Z_i is a vector of variables describing modeling decisions (i.e., $Z_i = (X_{Bi} \quad X_{Di} \quad X_{Ei})$, with γ a conformably dimensioned vector of parameters), and ϵ_i is a stochastic error.

The simple linear form of equation (6) has no intercept because we hypothesize that there is no fixed bias, independent of the modeling assumptions, in the estimates for consumer surplus per unit. The fixed bias will depend on the model used. Of course, variables may well t omitted, but these are more likely reflected i the error term, ϵ_i, because they likely vary wi each study. Substituting (5) into (6) gives tł basic form of the estimating model

$$(CS/v)_{Ei} = \beta\alpha_O + \beta\alpha_s X_{Si} + \beta\alpha_A X_{Ai} + \gamma Z_i + \epsilon$$

Under ideal conditions β would be unity.

An important element of an attempt to explai the results of applied economic research is tł development of hypotheses for the componen of Z_i. Following Hendry, if any economic mod is a strategy determined by the problem at har and the information available, then some el ments of modeling decisions (such as the trea ment of substitutes or the specification of tł opportunity cost of time) should play a role i the true demand function for a recreation sit But it is impossible to specify which assumptic is correct. Moreover, this judgment may deper on the application. Thus, studies that fail to re ognize these factors can be distinguished fro those that do, but a best strategy cannot be d termined for each case.

In applications of meta analysis in other di ciplines, an evaluation (by the meta analyst) (the experimental design, measurement proc dures, and controls is used to score the likel quality of each study's results to develop quali weights. These weights are applied to the resul from each study as part of the development (the statistical aggregate. This approach is not use here for two reasons. First, and most importan the correct treatment of the modeling judgmen inherent in most empirical economic research f a statistical summary depends on whether the affect the bias or variance in the estimate Weighting implicitly assumes that the estimate based on incorrect modeling judgments remai unbiased but simply have less information content (i.e., have higher variance). This ma be appropriate for summarizing controlled e periments, but it is less clear for economic a plications.

Second, modeling decisions may reflect se eral specific maintained hypotheses in each stud so developing weights would require scaling tł quality of these decisions. This is not possib given our current knowledge about how peop make recreation decisions.

With this background, we can distinguis variables that are largely associated with dat based decisions where little guidance is avai able in economic theory (those in X_D and X from those that are based on theory (X_B). As note

[3] While this estimator for (CS/v) has been commonly used in the literature, without checks to screen for negative values, it will not have finite moments (see Smith 1989).

earlier, from the perspective of transferring estimates from one applicaton to a new resource involved in a policy decision, it would be desirable if the data-based decisions played a small role in explaining variations in the CS/v estimates.

Results

Table 1 defines the specific variables used in explaining estimates of the consumer surplus per unit of use. $(CS/v)_{Ei}$ is measured by the real (constant dollar) consumer surplus per unit of use. Most of the variables are qualitative. Because $(CS/v)_{Ei}$ is derived from empirical models based on quite different data sets and estimation methods, it is reasonable to expect heteroskedasticity. Indeed, as Bockstael and Strand observed, it should be possible to estimate the variances in these estimates for the consumer surplus. However, two problems arise in implementing their suggestions with each of the demand specifications used in this study. First, the information routinely reported in travel cost demand studies is generally not sufficient to construct approximate estimates of the CS/v variances. Second, recent studies indicate that the approximations used in constructing these estimates can themselves be subject to important errors (Smith 1990, Kling and Sexton).

The panel nature of our data introduces other sources of nonspherical errors. For example, a simple random effects model would imply autocorrelation because results from different models reported within the same study share a common error. One could distinguish (in specifying the error process) whether the different estimates reported for each study reflected different modeling assumptions for the same site, the same basic model applied to different recreation sites, or some combination of these effects (as might be present in the regional travel cost models).

An estimator that accounts for the composite effects of all of these factors would require im-

Table 1. Description of Variables for Analysis

Name	Mean	Definition of Variables
(CS/v)	25.24	Marshallian consumer surplus estimated per unit of use, as measured by each study (i.e., per day or per trip) deflated by consumer price index (base = 1967).
Surtype	.86	Qualitative variable for measure of site use = 1 for per trip measure, 0 for per day measure.
Type of Recreation Activities		Water-based recreation (swimming, boating, fishing), hunting, wilderness hiking, and developed camping were identified as the primary activities. The first three are introduced as qualitative variables with developed camping as the omitted category.
Type of Recreation Site		Lake, river, coastal area and wetlands, forest or mountain area, developed or state park, national park with or without wilderness significance are the designations. Coastal area and wetlands was the omitted category. Variables are unity if satisfying designation, zero otherwise.
Substitute Price	.29	Qualitative variable = 1 if substitute price term was included in the demand specification, 0 otherwise.
Opportunity Cost type #1	.24	Qualitative variable for the measure used to estimate opportunity cost of travel time = 1 if an average wage rate was used.
Opportunity Cost type #2	.32	Qualitative variable for the second type of opportunity costs of travel time measure, = 1 for use of income per hour; the omitted category was the use of individual-specific wage rates.
Fraction of wage	.37	Fraction of wage rate used to estimate opportunity cost of travel time.
Specific Site	.24	Qualitative variable for use of a state or regional travel cost model describing demand for a set of sites = 1, 0 otherwise.
Demand Specifications		Linear, log linear and semilog (dep) are qualitative variables describing the specification of functional form for demand (semilog in logs of independent variables was the omitted category).
Year		The year of the data used in each study.
Estimators Used[a]		OLS, GLS, and ML-TRUNC are qualitative variables for estimators used, omitted cateogires correspond to estimators with limited representation in studies—the simultaneous equation estimators.

[a] ML-TRUNC refers to maximum likelihood estimators adjusting for truncation and tobit estimators. GLS includes both single equation generalized least squares and seemingly unrelated regressions.

posing considerable prior information to estimate the relevant variances and covariances for the estimates of $(CS/v)_{Ei}$ across studies. To avoid imposition of largely arbitrary assumptions, an alternative strategy is used. This involves estimating equation (7) with ordinary least squares (OLS) but reporting the Newey-West version of the White consistent covariance estimator for OLS in the presence of heteroskedasticity and generalized autocorrelation.[4] The results in table 2 indicate that the basic conclusions are largely unaffected by the standard errors used in significance tests for individual variables.

Table 2 reports the results for several models. The numbers in parentheses are the *t*-ratios calculated with the OLS standard errors, while those in brackets are the *t*-ratios using the standard errors from the adapted White consistent covariance matrix. The eight models illustrate different aspects of our summary. The first three ignore the role of recreation activities and focus exclusively on either assumption variables [column (1)], or site type variables [column (2)], or both [column (3)]. Column (4) expands the analysis in column (2) to include the primary recreational activities supported by the site. Columns (3) and (5) treat the definition of site type and primary recreational activities as alternative proxies for the same effects, and include the other variables describing the modeling strategies. Column (6) reports the most detailed model, and (7) reports the same model omitting only th variables reflecting data-based judgments. Th last column offers an alternative to (6), deletin the variable for the year of the study's data.

The variable "year" was included to invest gate whether recreational resources were grov ing more or less scarce over time.[5] Howeve this variable may also represent changes in th types of data, estimators, and methodologic advances over the time period of our review The influence of these factors as systematic re finements in methodology over time cannot b distinguished from a scarcity-related trend in th availability of recreation resources relative t demand. This trend effect on the relative valu is what one would like to evaluate for the sca city issue. The equations of the final model ir clude all types of effects, with and without th year variable. However, column (8) is probabl a better overall description [despite the statist cal significance of the year variable in the mod reported in column (6)] because of the consi tency in the parameter estimates with other le complete models and the consistent pattern c change in the variables describing each study characteristics when year is included.

The first five columns in table 2 explore th effects of missing values of particular classes c explanatory variables. While gaps and incor sistencies in reporting practices can be seriou obstacles to a meta-analysis of existing empir cal studies, the estimated effects of the variable

[4] A lag of eleven periods was used in implementing the Newey-West version of White's estimator.

[5] This analysis was suggested by an anonymous referee.

[a] The numbers in parentheses below the estimated parameters are the ratios of the coefficients to their estimated standard errors. The numbers in brackets use the Newey-West variant of the White consistent covariance estimates for the standard errors in calculating these ratios.

describing the modeling strategies are quite stable across the models we have estimated for CS/v. This judgment considers both their signs and statistical significance. Virtually all the decisions on the assumptions associated with qualitative modeling strategies were statistically significant factors in determining the real consumer surplus CS/v estimates.

When the variables are interpreted in terms of the classification used in developing equation (7), the key economic assumptions (such as the inclusion of a substitute price or measure of the implicit costs of travel time) are generally significant determinants of the estimate for the CS/v and conform to a priori expectations. The variable describing how site usage was measured indicates smaller benefits per unit in terms of days than trips. The parameter restrictions implicit in the use of a regional travel cost model appear to increase estimates of CS/v. This finding is difficult to explain based on prior theory. The restrictions imposed by the regional travel cost model have implications for the implicit extent of a recreation market, for whether sites are considered equivalent (by recreationists) in terms of the estimated demand responses to own price and income, and for the definition of what constitutes a substitute site.

The variables describing the functional form and estimator are classified as data based. This is based on our belief that analysts often engage in a pretesting process, either explicit or implicit. Results from different estimates are compared as part of the development of the "final" reported results. One way of evaluating the sensitivity of estimates to data specific judgments is to test the null hypothesis that the variables associated with these decisions do not exert a significant influence on CS/v. Using the sum of squared residuals for the models in columns (6) and (7), an F-test yields a decisive rejection of this hypothesis at the 1% significance level.

The effects of two variables deserve further discussion. The qualitative variable for the use of a maximum likelihood estimator (ML-Trunc) indicates whether the estimates attempt to adjust for the intercept nature of the data used in most microlevel recreation surveys. The negative and significant coefficient indicates that adjustment tends to reduce CS/v estimates. This probably reflects the evidence of the Smith and Desvousges (1985) study comparing ordinary least squares and a maximum likelihood estimator designed for truncation and censoring problems in an intercept survey (because it contributed a large number of the estimates for this evaluation). The second variable relates to the functional form specified for the demand model. Both loglinear and semilog specifications appear to increase CS/v over results with a semilog for the independent variables.

The type of recreation site and the primary activities supported by a site have distinctive effects. This finding requires careful interpretation because the site definitions are not mutually exclusive categories. For example, a trip to a lake in a national park would be worth \$19.94 more than one of the comparable length to a coastal area (i.e., the sum of the coefficient for national park, 41.13, and that of lake, −21.19 based on the model in column (8) of table 2). The results also suggest that wilderness sites and developed camping sites have similar consumer surplus estimates. This latter finding seems implausible, given the activities involved, and probably results from the small number of travel cost estimates for wilderness areas (i.e., about 10 of the 399 used in the models).

Implications

As the literature reporting benefit estimates for environmental resources expands, the task of summarizing what we know and how to use it in evaluating new policies becomes more difficult. The results reported here have implications for three types of questions. First, the studies under review span a period during which the conceptual models, data sets, and estimators for recreation demand analysis improved. Thus, they permitted an evaluation of the implications of a wide range of modeling judgments for consumer surplus (i.e., CS/v) estimates. Second, the studies also include an array of different types of recreation sites, allowing for the relative importance of the type of site for CS/v. Finally, the findings have implications for the feasibility of using econometric reviews of the empirical benefits literature in evaluating benefits transfer for policy analysis.

Overall, the results indicate that econometric methods can summarize the results from diverse empirical studies. Indeed, in our specific application (travel cost recreation demand models), this approach provided clear support for the issues identified in the theoretical and recent empirical literature as central to implementing the model. These include: (*a*) the implications of the treatment of an individual's time constraints for

his (or her) opportunity costs of time (Bockstael, Strand, and Hanemann); (*b*) the identification and treatment of substitute sites in modeling recreation demand (Rosenthal 1985, 1987); and (*c*) the adjustment of estimates from on-site microdata sets for the specification effects of these sampling procedures (Shaw).

The model selected as the best overall summary also provided some specific insights into the consequences of modeling judgments on each of these issues. For example, based on existing studies, use of an average wage rate or income per hour to measure the opportunity cost of time should reduce CS/v relative to its value with an individual-specific wage estimate. Equally important, the multiple used in the Cesario-Knetsch adjustment to wages has a significant effect on benefit estimates. The range is generally suggested to be between .25 and .50 with the usual value adopted about .33. Our model suggests this decision could lead to a $12.15 difference in the consumer surplus per unit of use. A failure to consider substitutes increases CS/v estimates. Finally, the effects of adjusting for the truncation effects of on-site surveys can be large, reducing the CS/v by over $50 from the OLS estimates.

Overall, meta-analytic summaries have considerable promise in evaluating the sensitivity of estimates of the values of nonmarketed recreation (and other environmental resources) to modeling assumptions. Because these studies generally have been based on site-specific data, econometric summaries of their findings are more likely to provide new insights than with macro applications where analysts often deal with the same aggregate data. Nonetheless, at this stage it would not be prudent to recommend this type of model for predicting CS/v for policy analysis. Rather, this approach can serve as a consistency check to the processes used in benefits transfer analyses for policy. More explicit use should await further research on the properties of meta-analytic summary models.

Theoretical and Empirical Advantages of Truncated Count Data Estimators for Analysis of Deer Hunting in California

Michael D. Creel and John B. Loomis

Truncated Poisson and truncated negative binomial count data models, as well as standard count data models, OLS, nonlinear normal, and truncated nonlinear normal MLE were used to estimate demand for deer hunting in California. The truncated count data estimators and their properties are reviewed. A large sample ($N = 2223$) allowed random segmenting of the data into specification, estimation, and out-of-sample prediction portions. Statistics of interest are therefore unbiased by the specification search, and the prediction results allow comparison of the statistical models' robustness. The new estimators are found to be more appropriate for estimating and predicting demand and social benefits than the alternative estimators based on a variety of criteria.

Key words: recreational demand, truncated count data models, travel cost models.

Surveys of users visiting a site are often employed to collect data on recreational demand. Given such a sampling method, no data will be collected for individuals taking zero trips to a site. The sample will therefore be truncated at the zero trip level. A second feature of recreation studies is that the dependent variable is often the count of the number of trips taken over the season or year. As such, it will be a nonnegative integer. The observed dependent variable is therefore the outcome of a data-generating process (DGP) based on some unknown probability distribution function defined on the nonnegative integers, which may be termed a count data process. The combination of a truncated sample from a count data process suggests that estimators based on truncated count data distributions may be called for.

Figure 1 illustrates the bias encountered in using an estimator which is uncorrected for sample truncation and shows what a count data process might look like. Let $Y = f(X, \beta, \epsilon)$, and let Y be distributed by some known count data process such that Y can take on the values $i \in \{0, 1, 2\}$. Assume that X is a matrix of nonstochastic independent variables, β is a parameter vector, and ϵ is a random disturbance. The heights of the curved lines above the lines $Y = i$ represent $p(Y = i|X, \beta)$. The heights of these lines sum to one in the vertical dimension. Line A represents $E(Y|X, \beta)$ and line B represents $E(Y|X, \beta, Y > 0)$. Assume a sample is taken from the population such that Y is observed only if $Y > 0$. The parameter estimates from a maximum likelihood estimator based on the known distribution of Y that is not corrected for the sample truncation will be biased and inconsistent since the regression will be approximating line B rather than line A. In the context of modeling demand, if Y is quantity and X is price, the uncorrected estimator's parameter estimates will most likely overstate Marshallian consumers' surplus because line B everywhere lies outside of line A. In most policy-relevant welfare economics problems, one wishes to estimate *ex ante* social benefits after changes in exogenous variables (e.g., site quality, season length) occur rather than estimate *ex post* benefits already received by the persons in the sample. Therefore, the population or unconditional demand curve (line

Funding for this study was provided by the Agricultural Experiment Station, Regional Research Project W-133 and the California Department of Fish and Game.

The authors would like to thank Jeffrey Grogger, Richard Carson, Cathy Kling, members of the W-133 Regional Research Project, and two anonymous reviewers for their helpful comments. As always, what follows is the sole responsibility of the authors.

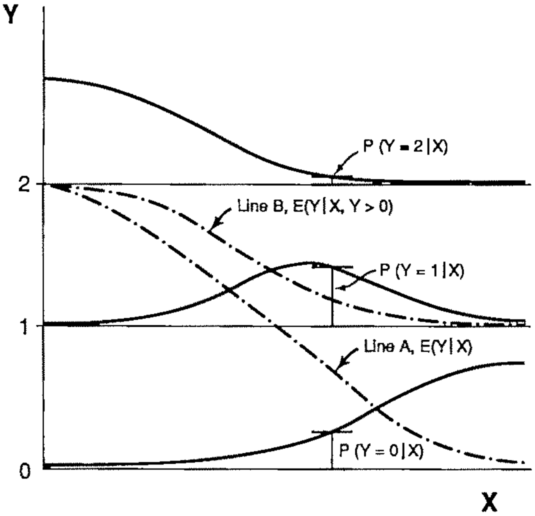

Figure 1. Truncation bias for a known count data process

A), should be the focus of interest. Shaw (1988b) presents a similar figure for the case of a normally distributed random variable. Truncation bias is further discussed in general by Maddala, and in the recreational demand literature by Smith, Desvousges, and Fisher; Smith; and McConnell and Kling.

Count data estimators may better fit data from a count data process than would a continuous distribution-based estimator. Count data estimators restrict positive probability assignment to possible events, while continuous distribution estimators give positive probability to fractional and possibly negative values of the dependent variable. The importance of respecting the count data nature of the dependent variable may depend on the problem at hand. As Larson shows, the normal distribution is a good approximation of the Poisson distribution if the Poisson parameter λ, which is usually parameterized such that λ_i is the conditional mean of the dependent variable Y_i, is large. Thus, if the DGP is truly a Poisson process, normal MLE may be a suitable procedure if the conditional mean of the dependent variable is large, but it may not give acceptable results if the conditional mean of Y_i is small. One should be cautious in using normal MLE to model a count data process for which small values of the dependent variable are common. A given count data distribution may be the true distribution underlying the DGP, but any continuous distribution is known a priori to be incorrect.

Poisson and negative binomial count data models have been used in numerous recent studies, including Hausman, Hall and Griliches' work on patents issued and Cameron and Trivedi's study of doctor visits. Smith employed a Poisson travel cost model to estimate demand for water-based recreation trips. Grogger and Carson (1987, 1988) introduced truncated Poisson and truncated negative binomial count data estimators. In their papers they present results of using standard untruncated count data estimators as well as their truncated estimators to estimate demand for fishing trips in Alaska. Finally, Shaw (1988a) presented a truncated Poisson estimator appropriate for endogenously stratified samples, and conducted some Monte Carlo simulations.

This paper presents results of employing Poisson (POIS), truncated Poisson (TPOIS), negative binomial (NB), and truncated negative binomial (TNB) maximum likelihood estimation as well as ordinary least squares (OLS), nonlinear normal (NLS), and truncated nonlinear normal (TNLS) MLE to estimate a travel cost method demand curve for deer hunting in California. A large sample (N = 2,223) was randomly segmented into specification, estimation and prediction portions. The following sections (*a*) present versions of Grogger and Carson's estimators for the case of truncation at the zero level and review their properties; (*b*) describe the specification-estimation-prediction methodology and present the estimation results; (*c*) compare the out-of-sample predictive performances of the models; and (*d*) give point estimates of consumers' surplus per trip for the various statistical models.

The Estimators

The Poisson probability law is

$$(1) \qquad f(W = w) = \frac{\exp(-\lambda)\lambda^w}{w!},$$

which is a discrete density function defined for w an element of the set of nonnegative integers. The parameter $\lambda > 0$ is both the mean and variance of the random variable W. If the elements of an $N \times 1$ (where N is the sample size) dependent variable vector Y are distributed independent Poisson (λ) and λ varies by observation as a function of an $N \times K$ matrix of explanatory variables X and a $K \times 1$ parameter vector β, as in

$$(2) \qquad \lambda_i = \exp(X_i\beta)$$

or, for the whole sample, in matrix notation:

$$(2.1) \qquad \lambda = \exp(X\beta),$$

then the standard Poisson likelihood function obtains:

$$(3) \qquad \ln L = -s'\lambda + Y'X\beta - s'\ln[Y!],$$

where s is an $N \times 1$ sum vector and the logarithmic and factorial functions are element-by-element.

Noting that $F(W = 0) = f(W = 0) = \exp(-\lambda)$, where $F(\cdot)$ indicates the cumulative density function (CDF) and $f(\cdot)$ indicates the probability density function (PDF), the conditional Poisson density function may be expressed as

$$(4) \quad f(W = w|W > 0) = \frac{\exp(-\lambda)\lambda^{w}}{w!}\left[\frac{1}{1 - \exp(-\lambda)}\right].$$

Maintaining the above notation and allowing λ to vary as in (2), the zero-level truncated Poisson likelihood function may thus be written as

$$(5) \quad \ln L = -s'\lambda + Y'X\beta - s'\ln[s - \exp(-\lambda)] - s'\ln[Y!].$$

A characteristic of the standard Poisson model is that the conditional mean of the dependent variable, λ, is equal to the conditional variance, i.e., the variance-mean ratio is unity. Overdispersion of the population is defined as the conditional variance of the dependent variable exceeding its conditional mean, giving a variance-mean ratio greater than unity. Overdispersion is thus a form of heteroscedasticity. If the population is overdispersed and the conditional mean is correctly specified as the true mean of the DGP, possibly as in (2), the untruncated Poisson model will give consistent estimates of the parameters but downwardly biased estimates of their standard errors (Gourieroux, Monfort, and Trognon 1984a, p. 707; Grogger and Carson 1987, p. 4). The truncated Poisson estimator is biased and inconsistent in the presence of overdispersion, since this estimator is based on the higher moments of the Poisson distribution through the CDF term in (4), which are incorrect given that the DGP embodies overdispersion (Grogger and Carson 1988, p. 7). Analogously, the standard Poisson estimator is biased and inconsistent when applied to a truncated sample since the conditional mean is misspecified as was illustrated in figure 1. The fact that both estimators are inconsistent if the sample is truncated and overdispersed makes the truncated negative binomial estimator an attractive generalization if these conditions are present.

The negative binomial probability law may be written as

$$(6) \quad f(Z = z) = \frac{\Gamma(z + 1/\alpha)}{\Gamma(z + 1)\Gamma(1/\alpha)}(\alpha\lambda)^{z}(1 + \alpha\lambda)^{-(z+1/\alpha)},$$

where $\Gamma(\cdot)$ indicates the gamma function. This is a discrete PDF defined for z, an element of the set of nonnegative integers, with parameters $\alpha > 0$ and $\lambda > 0$. The mean of the random variable Z is λ and its variance is $\lambda + \alpha\lambda^2$, which is everywhere greater than the mean. The variance-mean ratio is $1 + \alpha\lambda$, so the degree of overdispersion is an increasing function of both α and λ. This is the same distribution as found in Lee's equation 4.9 (Lee, p. 698) where our α is equivalent to Lee's $\delta/(1 - \delta)$. It may be derived by letting the Poisson parameter be distributed as a gamma random variable with mean λ and variance $\alpha\lambda^2$. As $\alpha \rightarrow 0$ the gamma distribution becomes degenerate and the negative binomial distribution reduces to a Poisson distribution. If the elements of the $N \times 1$ dependent variable vector Y are distributed independent negative binomial (λ, α) and λ varies by observaton as in (2) and α is an estimated constant for the population controlling the level of overdispersion, one of the possible negative binomial statistical models results with likelihood function given by

$$(7) \quad \ln L = s'\ln[\Gamma(Y + s/\alpha)] - s'\ln[\Gamma(Y + s)] - N\cdot\ln[\Gamma(1/\alpha)] + \ln(\alpha)s'Y + Y'X\beta - (Y + s/\alpha)'\ln[s + \alpha\lambda].$$

Note that for this density function,

$$(8) \quad F(Z = 0) = f(Z = 0) = (1 + \alpha\lambda)^{-(1/\alpha)}.$$

Bayes' theorem can be used to write the conditional negative binomial density function:

$$(9) \quad f(Z = z|Z > 0) = \frac{\Gamma(z + 1/\alpha)}{\Gamma(z + 1)\Gamma(1/\alpha)} \cdot (\alpha\lambda)^{z}(1 + \alpha\lambda)^{-(z+1/\alpha)}\left[\frac{1}{1 - (1 + \alpha\lambda)^{(-1/\alpha)}}\right].$$

Using the same notation as above and again allowing λ to vary as in (2), the zero-level truncated negative binomial likelihood function may be written:

$$(10) \quad \ln L = s'\ln[\Gamma(Y + s/\alpha)] - s'\ln[\Gamma(Y + s)] - N\cdot\ln[\Gamma(1/\alpha)] + \ln(\alpha)s'Y + Y'X\beta - (Y + s/\alpha)'\ln[s + \alpha\lambda] - s'\ln[s - (s + \alpha\lambda)^{(-1/\alpha)}],$$

where all operations other than matrix products are element by element.

Under a set of regularity conditions (Gourieroux, Monfort, and Trognon 1984b, appendix), the truncated Poisson and truncated negative binomial estimators will be consistent provided their conditional means are specified as underlies the true DGP (see Grogger and Carson 1987, appendix). If the dependent variable exhibits overdispersion, the truncated Poisson estimator will be inconsistent because its mean depends on the incorrect higher moments of the Poisson distribution, while the truncated negative binomial estimator will be consistent if the DGP is truly the above truncated negative binomial process and (2) is a correct specification of the population mean. Larson (pp. 171, 188) provides some diagrams which aid in understanding the differences between the count data models. The next section presents an application of these estimators as well as estimators based on the normal distribution to data of deer hunting in California.

Specification and Estimation

The data for this study were collected by a mail survey of California deer hunters who purchased a deer hunting license in 1987. There is no endogenous stratification in a mail survey (i.e., frequent visitors are no more likely to be sampled than infrequent visitors), so Grogger and Carson's estimators are appropriate rather than Shaw's truncated Poisson estimator. This paper focuses on hunters who took trips to one of seventeen X zones, one of the four types of hunting zones in California. X zones are located in northeastern California, for the most part. Before each hunting season, potential hunters (those persons with some propensity to hunt, though not necessarily currently active hunters) must decide whether or not to hunt. If the decision is to hunt, a license must be purchased. The license is valid for only one of the thirty-five hunt zones in California. If a license is purchased, the hunter may take as many trips to the zone as desired during the season, subject to a bag regulation.

We view this decision process as one of two stages. First a potential hunter decides which hunting zone is preferred, then the hunter decides how many trips to take to this zone. Site preference was modeled with a multinomial logit model, not discussed further in this paper. Hunters who preferred an X zone define the statistical population of the X zone trip frequency model, which is the focus of this paper. The unobserved zeros of the dependent variable (number of trips taken to an X zone) are a result of potential hunters who preferred to hunt in an X zone but decided not to purchase a license or, having purchased a license, failed to take any trips. A model treating hunters that visited non-X zones as observed zeros of an untruncated model of X zone visitation would be inappropriate for this problem, where there is no possibility of visiting other zones once the site preference decision has been made. This paper addresses only the trip frequency stage of the decision-making process. The seventeen X zones are treated as one destination, which may be thought of as imposing untested (but testable) coefficient restrictions across seventeen separate trip frequency models. This was done to facilitate comparing the statistical models and admittedly may not result in the best estimates for a particular X zone.

The general specification of the travel cost model was

$$(11)\quad Y_i = f(PRICES_i,\ SITE\ QUALITY_i,\ INDIVIDUAL\ CHARACTERISTICS_i,\ \phi,\ \epsilon_i)$$

or, in general matrix notation:

$$(12)\qquad Y = f(X, \phi, \epsilon),$$

where X is the matrix of independent variables ϕ is a vector of parameters (not limited to coefficients of independent variables), and ϵ is a vector of independent random disturbances. The dependent variable, Y, the number of trips taken to an X zone, is truncated at the zero level, as discussed above.

A candidate set of twenty explanatory variables was identified based on the above general specification; 2,223 survey responses contained valid observations of the entire set. The candidate set did not include travel costs to other sites due to the nonpossibility of substitution between sites after a license is purchased, as discussed above. These observations were randomly divided into three portions: a specification portion; an estimation portion; and a prediction portion of 707, 764, and 752 observations, respectively. The sample mean of the dependent variable, Y was 2.76 for the estimation portion of the data. This low mean suggests that the normally distributed specifications may provide a poor approximation to the true DGP.

The statistical models fitted were the following:

$$\text{OLS:}\qquad Y \sim N(X\beta, \sigma^2 I)$$

$$\text{NLS:}\qquad Y \sim N(\mu = \exp(X\beta), \sigma^2 I)$$

TNLS: $Y \sim N(\mu = \exp(X\beta), \sigma^2 I)$, Y observed only if $Y > 0.5$

POIS: $Y \sim Pois(\lambda = \exp(X\beta))$

TPOIS: $Y \sim Pois(\lambda = \exp(X\beta))$, Y observed only if $Y > 0$

NB: $Y \sim NB(\lambda = \exp(X\beta), \alpha)$

TNB: $Y \sim NB(\lambda = \exp(X\beta), \alpha)$, Y observed only if $Y > 0$.

The nonlinear truncated normal model is a standard lower truncated normal model as discussed in Maddala, with the exception of the nonlinear specification of the mean. The 0.5 lower truncation limit for the TNLS model was chosen as a continuity correction between the limits of 0 or 1, which, as Larson (pp. 296, 299) indicates, should allow the normal distribution to better approximate the unknown true count data DGP. Attempts were made to fit a linear ($\mu = X\beta$) truncated normal model, but convergence was not achieved. The count data models were as discussed above. Estimation programs written in the Gauss programming language are available from the authors.

Using the specification data, various combinations of explanatory variables and data transformations were used to fit all the statistical models. A semilog form (for the continuous distribution estimators, OLS, NLS and TNLS) gave a worse fit in all cases. Logarithms of continuous right-hand side (RHS) variables gave a slightly better fit in some cases, but were not used due to the arbitrariness of the resulting social benefit estimates. Quadratic forms of some variables (e.g., *AGE*, and *INCOME*) did not improve the results.

Ten independent variables including a constant were selected, based on theory and overall performance for each of the seven different statistical models. Some variables which were not significant for all of the statistical models were left in the final variable set to avoid omitted variable bias, as in the case of travel time. It would be possible to improve the fit of any of the models somewhat by selecting a model-specific set of variables, but in the interest of comparability a uniform set was chosen.

These variables were: *TC*, round trip travel cost at \$0.22 per mile, the sample average; *TIME*, round trip travel time in hours (experimentation using the specification data, with wage-weighting of travel time did not fit as well as time alone); *DAYS*, the individual's average length of trip; *YEARS*, the number of years the individual had previously hunted at the zone; *BAG*, a zero one dummy, equal to 1 if a deer was taken in the 1987 season; *PASNO*, the number of times the individual passed up an opportunity to take a deer; *DEERSN*, the number of deer seen on the last trip of the season; *INCOME*, household income in thousands of dollars; and *SEASON*, zone hunting season length in days.

Next, the above variables arrived at using the first portion ($N = 707$) of the data were used to estimate all the statistical models, using the estimation portion ($N = 764$) of the data. This was a one-time, first-try estimation for this data; therefore the results are free from any form of pretest bias. As such, the reported t-statistics and goodness-of-fit measures are unbiased by the specification search and are a fair means of comparing the statistical models' performance, insofar as the selection of included variables was fair. Estimation results are found in table 1.

All of the coefficient estimates are of the expected sign for all of the statistical models (a negative sign on the income coefficient is often encountered with travel cost models, see Duffield; Mendelsohn; or Grogger and Carson 1987, for instance). The truncated models are generally more elastic in all variables, which is expected, as in figure 1. In general, POIS is in closer agreement to NB than it is to TPOIS, and TPOIS is closer to TNB than it is to POIS. This suggests that the effect of truncation is more important than the effect of overdispersion. Given the significance of alpha, which reflects the level of overdispersion (see above) in the NB and TNB models, the hypothesis of no overdispersion can be rejected. The presence of overdispersion implies that the t-statistics of both POIS and TPOIS are biased away from zero, which may explain why they are almost always larger in absolute value than the corresponding t-statistics of the negative binomial models. Because the sample exhibits truncation and overdispersion the only potentially unbiased count data model is the TNB. Based on this fact and a good fit and t-statistics, the TNB statistical model seems superior to the alternative count data models. The OLS model is clearly inferior to the alternatives, while NLS and TNLS give results comparable to the count data models.

Prediction

The third step of the study was to use the coefficients estimated for the various statistical models using the estimation portion of the data to pre-

dict the number of trips taken in the prediction portion of the data ($N = 752$), conditional on the prediction portion's independent variables. This allows us to assess the robustness of the estimators and their relative usefulness in estimating consumers' benefits. Predictive ability is measured by R^2, by the difference between total predicted and total actual trips, and by percentage error. The prediction results are found in the upper portion of table 2.

Based on out-of-sample R^2, the count data models predict substantially better than do OLS and TNLS. TNLS performs strikingly poorly out-of-sample, achieving an R^2 of only 0.023 and overpredicting trips by 40.9%. NLS predicts about as well as the count data models. For all the statistical models, the difference between in-sample and out-of-sample R^2 is somewhat greater for the truncated models than for the corresponding untruncated models. In terms of predicting total trips taken, the POIS model is clearly superior, and TNLS is clearly inferior.

Benefit Estimates

Point estimates of consumers' surplus per predicted trip ($\hat{C}/\hat{Y}$) are found in the last line of table 2. As argued in the introduction, the unconditional population demand curve is usually of most interest in most welfare economics problems. Thus, for the truncated models, the results presented use the predictor $\hat{Y} = E(Y|X)$ rather than $\hat{Y} = E(Y|X, Y > 0)$. For OLS the formula is $\hat{C}/\hat{Y} = -\hat{Y}/(2\hat{\beta}_{TC})$, where $\hat{Y}$ is the predicted value of Y calculated at the means of the independent variables, and for all the other models the formula is $\hat{C}/\hat{Y} = -1/\hat{\beta}_{TC}$. These consumers' surplus figures are conditional on the site selection decision already having been made. Once a license is purchased, there is no possibility of substitution between zones. An alternative procedure would be to calculate welfare measures unconditional on site choice, using a joint site selection/trip frequency model. The truncated models give a lower estimate than do the corresponding untruncated models, as is expected from figure 1. This effect is most apparent in the NLS-TNLS pair. The truncated models attempt to fit the population unconditional demand curve analogous to line A of figure 1, while the untruncated models attempt to fit a line analogous to line B. For the count data models, allowing for overdispersion has little effect on the estimate, as is seen by comparing the pairs POIS-NB and TPOIS-TNB.

Conclusions

Several results are indicated by this study. First, accounting for truncation of the dependent variable makes a substantial difference in the coefficient estimates, and subsequently, in benefit estimates, regardless of the choice of statistical model.

Second, the TNLS model is not robust in the sense that it does not perform well out-of-sample, and it would be a poor choice to predict visitation. The conditional mean of this model is

$$(13)\quad E[Y|X, Y > 0] = \exp(X\beta) + \frac{\sigma\phi[(X\beta - .5)/\sigma]}{\Phi[(X\beta - .5)/\sigma]},$$

where $\phi[\cdot]$ and $\Phi[\cdot]$ are the density and distribution functions of a standard normal random variable, respectively. If the assumption of homoscedasticity is not justified, the parameter estimates of this model would be biased through the misspecified distribution function term in the likelihood function. If the DGP is characterized by the conditional variance increasing with the conditional mean, as is embodied in the count data models, the TNLS model will overcom-

Table 2. Out-of-Sample Prediction Results and Estimated Consumer Surplus

	Statistical Model						
	OLS	NLS	TNLS	POIS	TPOIS	NB	TNB

Note: Out-of-sample prediction results are prediction data, total actual trips = 1,845; estimated consumer results from estimation data.

pensate for truncation at low levels of the dependent variable, since σ will be too large and $\Phi[\cdot]$ will be too small. This overcompensation would serve to make the term $\exp(X\beta)$ in [13] small, which would tend to bias the price coefficient downward. This is reflected in the low consumers' surplus per trip estimate from this model. This bias may be sensitive to the number of outlying (large) observations of the dependent variable, which strongly influence the estimate of σ; this sensitivity would explain the lack of robustness exhibited by this model's spectacular overprediction of trips for the out-of-sample data.

A third result is that the data do appear to exhibit overdispersion. The hypothesis of no overdispersion (H0: $\alpha = 0$) is rejected with a high degree of confidence using either the NB or TNB models. Thus, the relatively large t-statistics of the POIS and TPOIS models should be viewed with suspicion, (recalling that these models' standard errors are biased downward if there is overdispersion) and bias suspected in the TPOIS model due to incorrect higher moments. The coefficient estimates of all the untruncated models are probably biased due to the sample truncation. Given these results, and given the poor performance of the TNLS model out-of-sample, the TNB model is the best suited of the models studied to estimating demand and social benefits for this data.

This paper has two messages. First, truncated count data models present a useful and perhaps better way to analyze a broad class of problems not limited to recreational demand. Second, the specification-estimation-prediction methodology should be more widespread. Elimination of specification bias and "clean" goodness-of-fit and t-statistics are necessary to evaluate a model, and they are positive aspects of the procedure. For smaller samples, the prediction step might be skipped (perhaps at the cost of failing to identify poor models such as the TNLS model here). The use of an entire large sample to both specify and estimate a model is an inefficient use of data in that bias is introduced to what are likely satisfactorily efficient estimates.

Elasticities in AIDS Models

Richard Green and Julian M. Alston

In the literature, a variety of approaches have been used to calculate demand elasticities in almost ideal demand system (AIDS) models of demand. It is common to estimate the linear approximate almost ideal demand system (LA/AIDS) instead of the AIDS. When the LA/AIDS is estimated, all of the previously reported approaches to compute elasticities are theoretically incorrect. This paper presents correct formulas for LA/AIDS elasticities and illustrates the potential errors from using incorrect computing formulas.

Key words: AIDS and LA/AIDS models, computing formulas, elasticities.

The almost ideal demand system (AIDS) of Deaton and Muellbauer (1980a,b) has become popular in recent years (Anderson and Blundell; Blanciforti and Green 1983a,b; Blanciforti, Green, and King; Chalfant; Eales and Unnevehr; Fujii, Khaled, and Mak; Fulponi, Heien and Willett; Murray; Parsons; Ray). A variety of approaches to computing elasticities has been used, and some of the approaches may lead to significant errors. This paper clarifies the differences between alternative approaches to estimating demand elasticities in AIDS models.

The AIDS Model

The AIDS model is usually specified as

$$(1) \qquad w_i = \alpha_i + \sum_j \gamma_{ij} \ln P_j + \beta_i \ln\left(\frac{X}{P}\right),$$

where X is total expenditure on the group of goods being analyzed, P is the price index for the group, P_j is the price of the jth good within the group, w_i is the share of total expenditure allocated to the ith good (i.e. $w_i = P_i Q_i / X$), and the price index (P) is defined as

$$(2) \qquad \ln P = \alpha_0 + \sum_j \alpha_j \ln P_j + \frac{1}{2} \sum_j \sum_i \gamma_{ij} \ln P_i \ln P_j.$$

The Linear Approximate AIDS (LA/AIDS) Model

Using the price index from equation (2) often raises empirical difficulties, especially when aggregate annual time-series data are used, and it is common to use Stone's (geometric) price index (P^*) instead of P:

$$(3) \qquad \ln P^* = \sum_k w_k \ln P_k.$$

The model that uses Stone's index is called the "linear approximate AIDS" (LA/AIDS) following Blanciforti and Green (1983a). If prices are highly collinear, P may be approximately proportional to P^*, i.e., $P \cong \zeta P^*$. In the extreme case when P is exactly (linearly) proportional to P^*, the LA/AIDS model can be used to estimate the parameters of the AIDS model because, then, the LA/AIDS can be written (in terms of the AIDS model parameters) as

$$(4) \qquad w_i = (\alpha_i - \beta_i \ln \zeta) + \sum_j \gamma_{ij} \ln P_j + \beta_i \ln\left(\frac{X}{P^*}\right).$$

More generally, however, the relationshp between the parameters of the AIDS and the corresponding parameters of the LA/AIDS is not known.[1] In addition, it is not known whether the LA/AIDS has satisfactory theoretical properties. These issues notwithstanding, the LA/AIDS is very popular.

Richard Green and Julian M. Alston are a professor and an assistant professor, respectively, Department of Agricultural Economics, University of California, Davis. Senior authorship is not assigned.

Giannini Foundation Paper No. 904.

The authors are thankful to Jim Chalfant and Mike Wohlgenant for helpful comments.

[1] The AIDS and the LA/AIDS are actually nonnested systems. However, as the Stone's index becomes a better and better proxy for the price index in (2), the estimates from the LA/AIDS would approach the estimates for the AIDS except for the intercept term.

Price Elasticities

A general definition of the uncompensated elasticities of demand from the AIDS and LA/AIDS (η_{ij}) is

$$(5)\quad \eta_{ij} = \frac{d\ln Q_i}{d\ln P_j} = -\delta_{ij} + \frac{d\ln w_i}{d\ln P_j} = -\delta_{ij} + \left\{\gamma_{ij} - \beta_i \frac{d\ln P}{d\ln P_j}\right\}\Big/ w_i,$$

where these elasticities refer to allocations within the group holding constant total group expenditures (X) and all other prices (P_k, $k \neq j$), δ_{ij} is the Kronecker delta ($\delta_{ij} = 1$ for $i = j$; $\delta_{ij} = 0$ for $i \neq j$) and for the LA/AIDS we use P^* from (3) instead of P from (2).

The differences in the literature can be represented in terms of different expressions for the elasticity of the group price index with respect to the jth price (i.e., $d\ln P/d\ln P_j$ or $d\ln P^*/d\ln P_j$). These differences carry over directly into the computation of compensated elasticities (η^*_{ij}), which are

$$(6)\quad \eta^*_{ij} = \eta_{ij} + w_j\left(1 + \frac{\beta_i}{w_i}\right).$$

In the AIDS model, the correct expression for the elasticity of the group price with respect to the jth price is

$$(7)\quad \frac{d\ln P}{d\ln P_j} = \alpha_j + \sum_k \gamma_{kj}\ln P_k.$$

Substituting (7) into (5) yields the correct elasticities for the AIDS. Several authors (e.g., Anderson and Blundell; Blanciforti and Green 1983a,b); Fulponi; Heien and Willett) have used the resulting computing formula for AIDS elasticities with parameters from the LA/AIDS.

To obtain the correct formula for the LA/AIDS, we differentiate Stone's price index with respect to the jth commodity price and get

$$(8)\quad d\ln P^*/d\ln P_j = w_j + \sum_k w_k \ln P_k \frac{d\ln w_k}{d\ln P_j}.$$

From (5) we have $d\ln w_i/d\ln P_j = \delta_{ij} + \eta_{ij}$, so that (8) may be written as

$$(8')\quad d\ln P^*/d\ln P_j = w_j + \sum_k w_k \ln P_k(\eta_{kj} + \delta_{kj}).$$

Notice the similarity between this expression for the LA/AIDS and equation (7) for the AIDS. An important difference is that when equation (8) is substituted into (5) or (6) the elasticity of interest is expressed in terms of itself and all of the other elasticities. In the case of n goods we have n^2 simultaneous equations for uncompensated demand elasticities of the form

$$(9)\quad \eta_{ij} = -\delta_{ij} + \frac{\gamma_{ij}}{w_i} - \frac{\beta_i}{w_i}\left\{w_j + \sum_k w_k \ln P_k(\eta_{kj} + \delta_{kj})\right\}.$$

Equation (9) can be expressed in matrix form as

$$(10)\quad E = A - (BC)(E + I),$$

where the typical elements are $a_{ij} = -\delta_{ij} + (\gamma_{ij}/w_i) - \beta_i(w_j/w_i)$ in A (an $n \times n$ matrix); $b_i = (\beta_i/w_i)$ in B (an $n \times 1$ vector); $c_j = w_j \ln P_j$ in C (a $1 \times n$ vector); and η_{ij} in E (an $n \times n$ matrix). Solving for the elasticities $[\eta_{ij}]$ yields, after some simplifications,[2]

$$(11)\quad E = [BC + I]^{-1}[A + I] - I.$$

Several authors have used computing formulas for the LA/AIDS that may be seen as special cases of this result. A common approach (e.g., Chalfant; Fujii, Khaled, and Mak) is to use equations for elasticities of the form $\eta_{ij} = -\delta_{ij} + \{\gamma_{ij} - \beta_i w_j\}/w_i$, which obtain in the special case when $d\ln P^*/d\ln P_j = w_j$ (i.e., expenditure shares are constant). As a further special case, Eales and Unnevehr use an elasticity formula corresponding to $\eta_{ij} = -\delta_{ij} + \gamma_{ij}/w_i$. This is compatible with both AIDS and LA/AIDS under the assumption that either preferences are homothetic ($\beta_i = 0\ \forall i$) or the group price is constant, independent of individual goods' prices (i.e., $d\ln P^*/d\ln P_j = 0$).[3] In their application the latter assumption is appropriate.

Table 1 summarizes the different approaches to estimating uncompensated price elasticities from the AIDS and the LA/AIDS. Clearly, all of the formulas are identical when budget shares are invariant with income (i.e., $\beta_i = 0\ \forall i$; pref-

[2] The steps are as follows. First, add an identity matrix (I) to both sides of (10) to get $(E + I) = (A + I) - (BC)(E + I)$. Then add $(BC)(E + I)$ to both sides to get $(BC + I)(E + I) = A + I$. Then premultiply by $(BC + I)^{-1}$ to get $(E + I) = (BC + I)^{-1}(A + I)$.

[3] Parsons uses a formula for compensated elasticities that is the same as Eales and Unnevehr's formula for uncompensated elasticities. We cannot see conditions under which Parson's formula could be correct.

Table 1. Uncompensated Price Elasticities for the AIDS and the LA/AIDS

Model	Uncompensated Price Elasticity Formula η_{ij}	Estimates for Food Group: Meats	Fruits & Vegetables	Cereal & Bakery Products	Misc. Foods
AIDS[a]					
	$-\delta_{ij} + \gamma_{ij}/w_i - \beta_i\alpha_j/w_i - \frac{\beta_i}{w_i}\sum_k \gamma_{kj}\ln P_k$	−0.994	−0.256	−0.799	−0.787
LA/AIDS[b]					
(i)	$-\delta_{ij} + \gamma_{ij}/w_i - \beta_i\alpha_j/w_i - \frac{\beta_i}{w_i}\sum_k \gamma_{kj}\ln P_k$	−0.411	−0.229	−0.736	−0.325
(ii)	$-\delta_{ij} + \gamma_{ij}/w_i$	−0.664	−0.200	−0.888	−1.066
(iii)	$-\delta_{ij} + \gamma_{ij}/w_i - \beta_i w_j/w_i$	−0.988	−0.255	−0.811	−0.764
(iv)	$-\delta_{ij} + \gamma_{ij}/w_i - \beta_i w_j/w_i - \frac{\beta_i}{w_i}\left[\sum_k w_k \ln P_k(\eta_{kj} + \delta_{kj})\right]$	−0.996	−0.255	−0.810	−0.761

[a] Estimates from Blanciforti, Green, and King.
[b] All of these models refer to parameters estimated by the LA/AIDS. Model (i) uses the AIDS formula (e.g., Anderson and Blundell); model (ii) corresponds to Eales and Unnevehr with $d\ln P^*/d\ln P_j = 0$; model (iii) assumes $d\ln P^*/d\ln P_j = w_j$ (e.g., Chalfant); model (iv) is the correct formula for LA/AIDS.

erences are homothetic). When preferences are not homothetic the formulas differ, perhaps in important ways.

Empirical Work

Next, we compare the empirical results from the AIDS model and the four alternative approaches to estimate elasticities from LA/AIDS parameter estimates. Full information maximum likelihood estimates of the AIDS applied to U.S. food consumption data are reported in Blanciforti, Green, and King (p. 36) and those results were used to calculate the AIDS elasticities. Using the same data we estimated the LA/AIDS.

Table 1 reports the alternative measures of uncompensated elasticities (at the means of the sample data) implied by these estimates using the alternative formulas.[4] As can be seen from table 1, the elasticity estimates for any commodity are similar across the AIDS and the LA/AIDS models (iii) and (iv); but the estimates are quite different using the LA/AIDS models (i) and (ii).

In this example, the correct LA/AIDS model (iv) provided similar elasticities to the AIDS model, and the error from using model (iii) (which treats shares as exogenous) was small. However, large errors result from using model (i) (i.e., the AIDS formula with LA/AIDS parameters) or model (ii) (i.e., assuming the price index is exogenous).

We checked the sensitivity of these results for autocorrelation. In the LA/AIDS model, the estimated autocorrelation coefficient was 0.9017 with an asymptotic t-value of 22.0. When the estimates are corrected for autocorrelation the estimated β_i values for the various food groups are −0.002, 0.002, −0.095, and 0.094. Thus, correcting for autocorrelation in this particular application essentially reduces the real income effect to zero and the differences in the various elasticity expressions vanish.

Conclusions and Future Extensions

When the LA/AIDS is estimated, we recommend using the theoretically correct formula which has been developed here. Researchers should employ the AIDS price elasticity formula only when they have estimated the AIDS. In our empirical work these two approaches led to essentially identical elasticity estimates. However, that may be an artifact of the particular data set we analyzed. Monte Carlo studies would be needed in order to establish the conditions under which the LA/AIDS provides a close approximation to the AIDS. The authors are currently engaged in further work exploring some of these issues.

[Received February 1989; final revision received August 1989.]

[4] Only the own-price uncompensated elasticities are reported. The cross-price elasticities and other details of the estimation are available from the authors.

The Demand for Cigarettes in Japan

Kim Haden

A two-stage budgeting procedure was used to estimate demand elasticities for cigarettes in Japan. Cigarettes were disaggregated into Japanese, U.S., and rest-of-world. Testing for habit effects was performed at both stages. Results indicated that habit effects occur for total expenditures on cigarettes but not between types.

Key words: cigarette demand elasticities, habit effects, Japan, two-stage budgeting procedure.

An increasing share of U.S. produced cigarettes has entered export markets over the last fifteen to twenty years (*Tobacco Quart.*). Although share increases have taken place, few empirical estimates of the demand for cigarettes in major importing nations have been reported. A good example is the cigarette market in Japan. While imported cigarettes make up a relatively small proportion of total cigarettes sold in the Japanese domestic market, the share of the Japanese market held by U.S. cigarettes increased by nearly 200% between 1964 and 1983. U.S.-manufactured cigarettes dominate the imported cigarette market in Japan, holding over 90% of the imported market. Japan is one of the top five importers of cigarettes from the United States. (*Tobacco Quart.*). Japan consumes virtually all imported and domestically manufactured cigarettes within the country, exporting very few cigarettes. Imports of tobacco have also increased over time, with the share of tobacco which is imported increasing from less than 10% to over 30% between 1964 and 1983. Given the declines in per capita consumption of cigarettes in the United States and the increasing share of cigarettes exported to Japan, estimates of elasticities of Japanese cigarette demand are of importance to policy makers, as well as to the U.S. cigarette and tobacco industries.

Japanese trade policies regarding imports of cigarettes during the last twenty years primarily consisted of a series of import tariffs. Prior to 1987, imports of cigarettes into Japan had tariffs placed upon them. Excise taxes were placed on cigarettes sold in Japan, whether imported or domestic.

The objectives of this study are twofold. The first objective is to estimate demand elasticities for cigarettes in Japan. The second objective is to determine whether or not consumption habits for cigarettes in Japan exist. Given that Japanese cigarettes and cigarettes manufactured in the United States hold the predominant share of the market, cigarette consumption in Japan is disaggregated into Japanese cigarettes, cigarettes from the United States, and cigarettes from the rest-of-world. Disaggregating cigarettes by country of origin is not implausible, because Japanese cigarettes are considered lower quality than U.S. cigarettes (*Tobacco Reporter*).[1] A two-stage budgeting procedure is employed to test whether habit effects exist at the level of share of income spent on cigarettes, and whether they exist at the level of share of cigarette expenditures spent on U.S., rest-of-world, or Japanese cigarettes. The procedure also allows for estimation of demand elasticities for the three types of cigarettes.

Methodology

The elasticity of demand for U.S. cigarettes has been investigated in several studies, and these studies provide some basis of comparison. Lyon and Simon estimated an arc elasticity close to −.5 for cigarette demand in the United States.

Kim Haden is an assistant professor, Department of Agricultural Economics and Rural Sociology, University of Tennessee, Knoxville.

The author gratefully acknowledges the helpful review comments by Greg Pompelli.

[1] One reason may be that the Japan Tobacco and Salt Public Corporation, the manufacturer of cigarettes in Japan, must purchase all of the domestic crop (Nath). The actual composition of Japanese cigarettes, in terms of domestic versus imported tobacco content, was not available. Very little tobacco is exported out of Japan; therefore, Japanese cigarettes likely contain Japanese tobacco.

Baltagi and Goel updated Lyon and Simon's quasi-experimental estimates, finding the elasticity had dropped between 1965 and 1983 to −.17. Other econometric studies have reported the own-price elasticity of demand for cigarettes in the United States at around −.5 (Fujii; Sumner and Wohlgenant; Lewit, Coate, and Grossman). Sumner and Alston estimated the U.S. domestic demand own price elasticity at about −.29. Fujii estimated cigarette demand in the United States and found lagged consumption to have a statistically significant influence upon current consumption.

This study employs a two-stage budgeting procedure to estimate demand elasticities. The two-stage procedure incorporates an almost ideal demand system (AIDS) to estimate the second stage.[2]

The AIDS model expresses w_i, the ith budget share, as

$$(1)\quad w_{i,t} = \alpha_i + \sum_j \tau_{ij} \ln p_{j,t} + \beta_i \ln(X/P)_t, \qquad \text{for all } i,\ t = 1 \ldots T,$$

where $w_{i,t}$ is the expenditure share of the ith commodity in period t, $p_{j,t}$ are prices in period t, X is the total expenditure on all commodities in the system, and P_t is a price index, such that

$$(2)\quad \ln P_t = \alpha_o + \sum_k \alpha_i \ln p_{k,t} + 1/2 \sum_k \sum_j \tau_{kj}^{*} \ln p_{k,t} \ln p_{j,t}.$$

In this study, $w_{i,t}$ represents the expenditure share on the ith type of cigarette, including U.S., rest-of-world, and Japanese cigarettes.

The index, P_t, may be replaced by a linear approximation in the form of a geometric index, P_t^*, to produce a linear approximation of the system (Deaton and Muellbauer 1980a). The index, P_t^*, is defined so

$$(3)\quad \ln P_t^* = \sum_k \bar{w}_k \ln p_k,$$

where $\bar{w}_k$ is the mean of the budget share. Therefore, the approximation of (1), is

$$(4)\quad w_{i,t} = \alpha_i^* + \sum_j \tau_{ij} \ln p_{j,t} + \beta_i \ln(X/P^*)_t.$$

Blanciforti, Green, and King call this model the "linear approximate almost ideal demand system".

Two recent studies incorporated dynamic adjustment into the AIDS model (Eales and Unnevehr; Blanciforti, Green, and King). Eales and Unnevehr use a set of first differenced share equations. However, this formulation is somewhat restrictive. Several general forms for the share equations are suggested by Blanciforti, Green, and King, with one including a lag of per capita consumption of the good in the share equation and another form including a lag of the share in the share equation. The latter may be expressed as

$$(5)\quad w_{i,t} = \alpha_i^* + \alpha_i^{**} w_{i,t-1} + \sum_j \tau_{ij} \ln p_{j,t} + \beta_i \Big\{ \ln X_t - \alpha_o - \sum_j (\alpha_k^* + \alpha_k^{**} \tau_{k,t-1}) \ln p_{k,t} + 1/2 \sum_k \sum_j \tau_{ij}^{*} \ln p_{i,t} \ln p_{j,t} \Big\}, \qquad \text{for all } i,\ t = 1 \ldots T,$$

where $w_{i,t-1}$ is the expenditure share of the ith commodity in period $t - 1$. Autocorrelation of the error terms from a static AIDS model may indicate some type of misspecification of the model. Blanciforti, Green, and King cite autocorrelation of the error terms of the share equations of a static AIDS model as evidence that a specification which incorporates habit effects may be needed.

When a one-period lag of the share is incorporated on the right-hand side of the share equations, the theoretical demand restrictions will hold only at local values of $w_{i,t-1}$ for the coefficients of the dynamic AIDS model (Blanciforti, Green, and King).

The formulas for expenditure and price elasticities are

$$(6)\quad \mu_i = 1 + \beta_i / w_i, \text{ and}$$

$$(7)\quad e_{ij} = w_i^{-1} \left[\tau_{ij} - \beta_i \left(\alpha_j + \sum_k \tau_{kj} \ln p_k \right) \right] - \delta_{ij},$$

[2] An alternative system which is commonly used is the Armington model. However, the Armington model imposes a severely restrictive set of assumptions, including separability among import sources (Alston et al.).

where δ_{ij} is the Kronecker delta. The estimates for β_i, α_j, τ_{ij}, and τ_{kj} can be obtained from the linear approximate model.

The first stage of the budgeting procedure is hypothesized to be

$$(8) \quad M_t = \Phi_0 + \Phi_1 M_{t-1} + \Phi_2 \ln P_t^* + \Phi_3 \ln Z_t + \Phi_4 \ln Y_t + \Phi_5 YR,$$

where M_t is the share of per capita income expended on all cigarettes in the system in period t, M_{t-1} is the expenditure share in period $t - 1$, P_t^* is as defined previously, Z_t is an index of prices of goods other than cigarettes which make up the consumer's budget, Y_t is per capita income in period t, and YR is a time trend to reflect changes in health concerns and tastes and preferences. Notably, the share of income spent on cigarettes is a function of last period's share. Therefore, (8) implies that adjustments in expenditure share on all cigarettes to changes in income and prices are only partial within one period. While (8) implies adjustment at the level of share of income expended on all cigarettes, (5) implies adjustment in cigarette expenditure shares between cigarette types. Hence, the effects of habit can be distinguished at two levels.

The elasticity of expenditures on all cigarettes with respect to income, Ω, is found by

$$(9) \quad \Omega = 1 + \Phi_4/M,$$

where Φ_4 is from (8) and M is the share of income expended on cigarettes.

Income elasticities for the different types of cigarettes can be found by

$$(10) \quad \theta_i = \mu_i \cdot \Omega,$$

where θ_i is the income elasticity for the ith type of cigarette, μ_i is the expenditure elasticity for the ith type of cigarette, and Ω is the elasticity of expenditures on all cigarettes with respect to income.

Data

Data were gathered for the years spanning 1964–83. The years beyond 1964 were chosen because they followed the Surgeon General's report on smoking and health (Pugh).[3] Data for some variables found in the *Japan Statistical Yearbook* (Japan) were not available beyond 1983. Data for prices and quantities of imported cigarettes were gathered from *Commodity Trade Statistics* (UN FAO). Retail prices were unavailable for imported cigarettes, so prices at import with import tariffs and excise taxes added were used as proxies. Therefore, prices of U.S. cigarettes and rest-of-world cigarettes may be understated from their retail values.

Information regarding tax and tariff rates on cigarettes were obtained from the Japanese Embassy. Exchange rates were found in *International Financial Statistics* (UN FAO). All other data was gathered from the *Japan Statistical Yearbook* (Japan). An index of consumer food prices was used for Zt.[4] The proxy for Japanese retail price of cigarettes was the Tokyo price of one of the top selling brands (*Tobacco Reporter*, Jan. 1980). All prices were converted to yen per pack and were deflated by the Japanese CPI, and consumption was in packs per person per year. The measure of income, Yt, was gross national product per person, in yen.

Estimation and Testing

The system of equations for the second stage, including share equations for Japanese cigarettes, U.S. cigarettes, and rest-of-world cigarettes, was estimated using a static AIDS model, with homogeneity and symmetry imposed. The static model was estimated using iterative seemingly unrelated regressions, which produces results equivalent to maximum likelihood (Kmenta). The error terms from the estimated equations contained no statistical evidence of serial correlation, suggesting that a dynamic formulation in the second stage was unnecessary. Furthermore, when lags of the budget shares were incorporated, none of the coefficients on the lags were significantly different from zero. Multicollinearity diagnostics showed no strong indication that the lagged shares introduced degrading collinearity into any of the equations. Also, when lagged per capita consumption of each of the types of cigarettes was introduced as the measure of habit formation, negative serial correlation was introduced into the residuals from each of the equations indicating misspecification of the model. The estimated model is shown in table 1. All of the coefficients were signifi-

[3] Although Japan has fewer restrictions than the U.S. toward use of smokables, the Surgeon General's report was followed by large increases in imports of lower nicotine tobacco versus higher nicotine tobacco (*Tobacco Reporter*, Jan. 1980).

[4] Because an index for prices of consumer goods other than cigarettes was not available, a price index of a commodity group which makes up a large portion of the consumer's budget, food, was used. This implies the assumption that the commodity groups of cigarettes and food are separable.

Table 1. The Demand System for Cigarettes in Japan

	Estimated Coefficients						
Cigarette Group i	a_i	β_i	τ_{i1}	τ_{i2}	τ_{i3}	R^2	Durbin-Watson d
(1) U.S. cigarettes	−.2268	.0514	−.0040	.0093	−.0053	.8143	1.645
	[.0440][a]	[.0087]	[.0043]	[.0021]	[.0045]		
	(−5.154)[b]	(5.908)	(−.930)	(4.428)	(−1.177)		
(2) Rest-of-world cigarettes	.0406	−.0082	.0093	−.0055	−.0038	.8407	1.761
	[.0188]	[.0038]	[.0021]	[.0021]	[.0017]		
	(2.159)	(−2.157)	(4.358)	(2.619)	(−2.235)		
(3) Japanese cigarettes	1.1862	−.0432	−.0053	−.0038	.0091	.5636	1.608
	[.0500]	[.0097]	[.0045]	[.0017]	[.0055]		
	(23.724)	(−4.453)	(−1.177)	(−2.235)	(1.654)

[b] Values in the parentheses are the t-statistics.

cantly different from zero at the .10 level except for the U.S. and Japanese cross-price coefficients and the coefficient on own-price in the U.S. and Japanese equations.[5]

The estimated equation for the first stage is

(11)

$$
\begin{array}{llll}
M_t = & -.33198 & +\ .22452\, M_{t-1} & +\ .00698 \ln P_t^* \\
 & [.07836] & [.05964] & [.00070] \\
 & (-4.327) & (3.764) & (9.997) \\
 + & .015124 \ln Z_t & -\ .00986 \ln Y_t & +\ .00015\, YR \\
 & [.00505] & [.00091] & [.00003] \\
 & (2.989) & (-10.759) & (5.221)
\end{array}
$$

$$R^2 = .9969 \quad \text{Durbin } h = .8751.$$

The coefficient on the lagged expenditure share was significantly different from zero, and at .22452 indicated an adjustment coefficient of .77548. The hypothesis that the adjustment coefficient was equal to zero was rejected. The coefficient on income also was significantly different from zero and had a negative sign. Using the estimated coefficient on the logarithm of income in equation (11) and the average budget share of cigarettes, the estimate for the elasticity of cigarette expenditures with respect to income is .1682. The elasticities of cigarettes with respect to income and with respect to cigarette expenditures are presented in table 2. The income elasticities for U.S. and Japanese cigarettes were positive, while the income elasticity for rest-of-world cigarettes was negative.

The own-price elasticities, also presented in table 2, were of the expected sign for all equations. The own-price elasticity for U.S. cigarettes was much less than that for Japanese cigarettes or rest-of-world cigarettes. The own-price elasticity on U.S. cigarettes sold in Japan is fairly similar to values which have been estimated for the own-price elasticity in the U.S.

As shown in table 2, positive cross-price elasticities indicated that Japanese and rest-of-world cigarettes were substitutes. They also indicated that U.S. and rest-of-world cigarettes were substitutes. The cross-price elasticities between cigarettes from the United States and Japan had a negative sign suggesting complementarity.

Conclusions

The elasticities suggest that U.S. and Japanese cigarettes may be considered normal goods, with U.S. cigarettes having a greater elasticity with respect to income than Japanese cigarettes. However, rest-of-world cigarettes are inferior goods. The elasticity estimates also imply that Japanese and rest-of-world cigarettes are substitutes. The own-price elasticities point towards more price responsiveness of consumption of rest-of-world cigarettes and Japanese cigarettes than of consumption of U.S. cigarettes.

The negative signs on the cross-price elasticities between U.S. and Japanese cigarettes are puzzling, particularly in light of the fact that the signs and magnitudes of the other elasticities seem plausible. The signs on the cross-price elasticities may perhaps indicate problems with the specification used. Pitts and Herlihy suggest that where there is a fairly fixed expenditure for a commodity group, or fixed volume of consumption, and the absolute values of the own-price elasticities are less than one, perverse sub-

[5] Because insignificant coefficients occurred, multicollinearity diagnostics were performed on all three equations. No strong evidence of degrading collinearity was found for any of the three equations.

Table 2. Elasticities of Demand for Cigarettes in Japan

Cigarette Group i	Income (θ_i)	Expenditure on Cigarettes (μ_i)	Uncompensated Price of Group i with Respect to Group j (e_{ij}) U.S.	Rest-of-World	Japanese
(1) U.S. cigarettes	.5950	3.5380	−.5631[a]	.3517	−2.9541
(2) Rest-of-world cigarettes	−.0432	−.2569	1.2130	−1.7902	.8806
(3) Japanese cigarettes	.1607	.9556	−.0076	.0019	−.9483

[a] All elasticities were calculated using only coefficients which were significantly from zero at the .10 level.

stitution relationships may result between commodities in the group.[6]

No habit effects could be found at the level of expenditure shares between types of cigarettes, implying that consumers adjust their expenditure shares completely in one time period to changes in prices and income. Habit effects could, however, be seen at the level of share of income spent on cigarettes. This suggests that, while consumers have little habit formation between the types of cigarettes, there is significant formation of habits in regards to total expenditures on cigarettes. These findings imply that, while Japanese consumers have not developed a habit formation for U.S. cigarettes, as compared with other types, neither have they developed habits specifically for Japanese cigarettes.

[6] They hypothesize that when the absolute values of own-price elasticities of the goods are less than one and the expenditures on the commodity group are fairly fixed, as the price of one of the goods goes up the consumer may decrease the consumption of both.

Quasi-Experimental Price Elasticity of Liquor Demand in the United States: 1960–83

Badi H. Baltagi and Rajeev K. Goel

This paper uses sixty-five recent tax changes on liquor in private licensed states over the period 1960–83 to update Simon's quasi-experimental price elasticity of liquor. Three alternative measures for liquor price are used, and the sensitivity of this price elasticity to border effect purchases as well as market changes over time are examined. Our results support a liquor price elasticity estimate of −.7. However, the confidence interval on this estimate is wide. Border effect purchases as well as changes in the liquor market over time are statistically insignificant.

Key words: bootlegging, liquor demand, quasi-experimental price elasticity.

The price elasticity of liquor demand is important for policy makers trying to assess the effect of a change in liquor taxes on tax revenues. [Distilled Spirits Council (DISCUS) estimates the federal, state, and local revenues from distilled spirits to be $6.9 billion in 1983, 14% higher than in 1973, and nearly twice as much as in 1963.] This liquor price elasticity is also important for the liquor industry in determining the effect of a new tax on industry sales and profits. [The Liquor Handbook (Jobson Associates) reports that 157.4 million cases of distilled spirits were sold in the U.S. in 1983, and the Brewer's Almanac reports a 1.84 gallons per person consumption of distilled spirits in the U.S. for 1983.] Furthermore, this price elasticity can be used for studying public health issues as well as criminal activity related to alcohol consumption. In fact, Cook used this price elasticity to determine the effectiveness of liquor taxes in reducing consumption of liquor- and alcohol-related deaths, like auto fatality rates and cirrhosis of the liver.

One approach to estimating this price elasticity involves the specification and estimation of demand for liquor (see McGuinness for an econometric analysis of liquid demand in the United Kingdom; Clements and Johnson for Australia; Johnson and Oksanen 1974, 1977 for Canada; Niskanen; Wales, Smith, and Cook and Tauchen for the United States). Estimates of the price elasticity of liquor for the United States from this approach range from −2.03 by Niskanen to 0.08 by Wales, (see Ornstein for a survey). Alternatively, one can apply Simon's (1966b) quasi-experimental method to estimate this price elasticity. This method is well suited for commodities that have fairly constant prices that change only due to a tax change. It does not require the specification of a demand function and, because it is tailored around a tax change, the price elasticity is computed over a well-defined period. This approach yields a liquor price elasticity of −.79 for the period 1950–61. Since then, the period 1961–82 brought about an additional sixty-five tax changes on liquor in private licensed states.

This paper uses these tax changes to update Simon's quasi-experimental price elasticity of liquor over this recent period. This paper also checks the sensitivity of this elasticity estimate to alternative measures of liquor price and border effect purchases.

Methodology and Results

Simon (1966b) proposed the following price elasticity computation for each trial state that

Badi H. Baltagi is a professor of economics at Texas A&M University; Rajeev K. Goel is an assistant professor of economics at Illinois State University.

The authors would like to thank Dan Hecht for providing missing observations in the data. They would also like to express their gratitude to two anonymous referees for their helpful comments.

experienced a tax change:

$$\varepsilon_p = \left[\{(Q_2 - Q_1)/Q_1\} - \left\{ \sum_{i=1}^{n} (Q_{2i}^* - Q_{1i}^*)/Q_{1i}^* \right\} \Big/ n \right] \div \{(P_2 - P_1)/P_1\},$$

where P_1 and Q_1 denote the price and per capita consumption for the year ending before the tax change in the trial state. For liquor, Simon suggests leaving a period of three months before and five months after the price change to avoid the stock-up and liquidation effects that are associated with a tax change. P_2 and Q_2 denote price and per capita consumption for the year beginning after the tax change in the trial state. Q_{1i}^* and Q_{2i}^* denote per capita consumption for the relevant before and after periods for the ith comparison state, $i = 1, 2, \ldots, n$. A comparison state is any state where price did not change during the relevant period.

Simon (1966b) calculated the price elasticity of liquor using twenty-three price changes over the period 1950–1961. These price changes occurred in private licensed as well as monopoly states. Private licensed states denote states with privately owned liquor stores that are licensed by the state. Monopoly states have a legal monopoly on the wholesale or retail of liquor. For more on the effects of the two governmental systems on prices, revenues and consumption of liquor, see Simon (1966a). The median price elasticity reported is −.79 with a 96.5% confidence interval of (−.97, −.03). These calculations excluded the moonshine states, the District of Columbia, and two anomalous states that were not identified. In addition, Simon (1966b; p. 196) excluded price changes that are less than 2%.

In updating this elasticity, we consider sixty-five tax changes that occurred in private licensed states between 1961 and 1982. These are reported in the Distilled Spirits Council of the United States. Over this period the federal excise tax on liquor was constant at $10.50 (per proof gallon). The federal excise tax on liquor was raised to $12.50 per proof gallon on 1 October 1985. Simon (1966b, p. 196) suggests excluding price change events that occur within eighteen months before or after a federal tax change. Data availability together with the discontinuity introduced by a federal tax change forced us to restrict our sample until 1983. We also excluded all price changes that were less than 2%, the moonshine states, the monopoly states and the District of Columbia.

Consumption data for liquor (in gallons per capita) for each state are available from various issues of the *Brewers Almanac*. These data have been criticized on grounds that they are based on reports of wholesalers to the tax authorities. This consumption may differ from actual consumption because of moonshine activities in that state, underreporting by wholesalers to reduce their taxes, and border effects purchases, where commuters buy from an adjacent state with lower prices (Cook, Wales, Smith). Carlson (p. 31) reports that "about 55% of New Hampshire's $155 million in annual liquor sales is to out-of-state tipplers." Although we are unable to account for the underreporting phenomenon, we do exclude the moonshine states and vary the comparison states to deal with the border effects. This is done by excluding from the comparison group all states that are neighboring a state with a tax change. Removing these neighboring states should reduce the border effect bias, (Baltagi and Goel).

The data on the price of liquor are harder to find than the data on quantity. Simon (1966b, p. 197) used the price of Seagram 7 Crown because it is the largest selling brand and because it "is commonly used as a standard in the liquor industry." Data on this and eight other leading brands are available from yearly issues of the *Liquor Handbook* (Jobson Associates). These nine leading brands are Blend (Seagram 7 Crown), Straight (Old Crow), Bond (Old Forester), Scotch (Haig & Haig), Canadian (Seagram V.O.), Gin (Gordon's), Rum (Bacardi), Brandy (Christian Brothers), and Vodka (Smirnoff 80°). Three alternative measures for the price of liquor were used in this study: (*a*) the retail price of a fifth of Seagram 7 Crown; (*b*) a Laspeyres price index based on all nine brands with the quantities sold of each brand in 1972 serving as the base quantities; (*c*) a Paasche price index based on all nine brands with the prices of each brand in 1972 serving as the base prices. If some of the prices or quantities were missing, these indices were computed for all available brands. In fact, in all but seven cases these indices were based on five or more brands.

Table 1, panel A, gives the quasi-experimental price elasticity of demand based on these three measures for the price of liquor. The median price elasticity based on Seagram 7 Crown is −.924 compared with −.744 for the Paasche index and −.771 for the Laspeyres index. These elasticities are based on 35, 48, and 47 observations, respectively. This disparity in the number of observations is the result of missing data. Al-

Table 1. Quasi-Experimental Price Elasticities of Liquor Demand with and without Correction for the Border Effects: 1960–82

Price Measure:	Seagram 7 Crown	Paasche	Laspeyres
A. No correction for border effects			
Median	−.924	−.744	−.771
95% C.I. for the median[a]	(−1.160, −.602)	(−1.133, −.386)	(−1.249, −.503)
n	35	48	47
B. Corrected for border effects			
Median	−.779	−.616	−.629
95% C.I. for the median[a]	(−1.171, −.613)	(−1.214, −.166)	(−1.228, −.256)
n	35	48	47

[a] This confidence level is slightly larger than 95%, depending on the sample size; see Nair. For example, when n = 47, this is a 96% confidence interval.

though the latter two elasticities are lower than the Seagram 7 Crown elasticity, we fail to reject the fact that they are not significantly different from each other. A paired t-test was computed for the Seagram 7 Crown elasticity and the Paasche elasticity. The observed t-statistic is −.11, which is not statistically significant. Similarly, the paired t-test for the Seagram 7 Crown elasticity and the Laspeyres elasticity turns out to be −.35, which is again not statistically significant. Our Seagram 7 price elasticity of −0.924 for 1960–82 is higher than −0.79 reported by Simon for 1950–61. Some explanations for this increase in elasticity in recent years include greater health consciousness, health warnings, and education programs by organizations such as Mothers Against Drunk Driving. However, Simon's −.79 price-elasticity falls in the confidence interval reported in table 1 and our −.92 price-elasticity estimate falls in Simon's confidence interval. Also, Simon's −.79 estimate is not much different from the Paasche and Laspeyres elasticities.

Next, the sensitivity of this elasticity to the 'border effect' problem is considered. Table 1, panel B, calculates the same elasticities as in panel A; the only difference is a change in the comparison group. In fact, the new comparison group excludes all states that are neighboring any state with a tax change. The median price elasticities for the no neighbors comparison group are −.779, −.616, and −.629 for the Seagram 7 Crown, the Paasche, and the Laspeyres price elasticities, respectively. These border effect corrected elasticities are smaller than the corresponding ones obtained without this correction. However, this difference is not statistically significant. A paired t-test for the Seagram 7 Crown price elasticity with and without the neighboring states in the comparison group, yields an observed t-value of −.49 which is not statistically significant at the 5% level. Similarly, the Paasche and Laspeyres paired t-tests yield t-values of −.61 and −1.03, respectively. These results suggest that correcting for the border effect reduces the price elasticities. However, these reductions are not statistically significant.

Finally, we check the sensitivity of these elasticities to changes in the market over time. The observation period is split into two parts: 1960–69 and 1970–82. The results indicate lower price elasticities for the second period for all price measures considered. However, this difference is not statistically significant. (These are available upon request from the authors.)

Conclusion

This paper updated Simon's (1966b) price elasticity for liquor demand for the period 1960–83. This price elasticity was lower when a Paasche or Laspeyres price index was used instead of the retail price of Seagram 7 Crown (−.74 and −.77 compared to −.92). However, this difference was not statistically significant. These elasticities were also reduced by correcting for the border effect bias (−.62, −.63, and −.78, respectively). Again, this reduction was statistically insignificant. The lack of statistical significance for the liquor price elasticity with respect to border effect purchases is contrasted with an opposite occurrence for cigarette demand where the border effect was significant (Baltagi and Goel). A liquor price elasticity of about −.7 is supported by our results, even though the confidence interval is wide. This means that there is room for raising revenues by taxing liquor, but the reduction in alcohol consumption is not certain since consumers may switch to wine or beer.

Whither Armington Trade Models?

Julian M. Alston, Colin A. Carter, Richard Green, and Daniel Pick

The Armington trade model distinguishes commodities by country of origin, and import demand is determined in a separable two-step procedure. This framework has been applied to numerous international agricultural markets with the objective of modeling import demand. In addition, computable general equilibrium (CGE) models commonly employ the Armington formulation in the trade linkage equations.

The purpose of this paper is to test the Armington assumptions of homotheticity and separability with data from the international cotton and wheat markets. Both parametric and nonparametric tests were performed, and the empirical results reject the Armington assumptions. This has important implications for international trade modeling and CGE modeling.

Key words: Armington, cotton, homotheticity, nonparametric tests, separability, wheat.

The responsiveness of import demand to international price changes is an important topic in applied international agricultural trade research. Elasticities of import demand are used commonly to estimate the effects of trade barriers and to examine trade policy options. Interest in the topic was renewed during the 1985 debate over the U.S. Food Security Act. In fact, the price responsiveness of import demand for U.S. agricultural sales became the single most important issue in the policy debate (Thompson 1988). Ultimately, the U.S. government decided that the import demand for U.S. agricultural exports (such as cotton and wheat) was price responsive. Foreign import demand elasticities in excess of unity were then used to justify lowering U.S. loan rates (i.e., floor prices) in attempting to regain market shares in the international markets (FAPRI, Myers).

Empirical estimates of import demand elasticities are predicated on the specification chosen for the trade model. A number of different model specifications have appeared in the literature, and these are well documented in two separate surveys by Sarris (1981) and Thompson (1981). The Armington model is a popular specification. It is a disaggregate model which distinguishes commodities by country of origin with import demand determined in a separable two-step procedure. The Armington approach permits the calculation of cross-price elasticities between imports from all sources using estimates of the aggregate price elasticity of demand for imports, a single elasticity of substitution and trade shares. Ease of use and flexibility are two reasons why the Armington model has been applied so often to international agricultural markets. Of course, another important reason is that the Armington model often gives results which are judged to be successful because of both plausible parameter estimates and statistical significance.

The Armington approach has been applied to modeling agricultural trade by Abbott and Paarlberg; Babula; Figueroa and Webb; Grennes, Johnson, and Thursby; Johnson, Grennes and Thursby; Penson and Babula; Sarris (1983); Suryana; Webb et al. In addition, it has been accepted as the appropriate way in which to model trade flows in a computable general equilibrium (CGE) model (de Melo and Robinson 1981, 1985) and has been used extensively in CGE models of international trade in agricultural products (e.g., Adelman and Robinson).

The Armington model assumes that import demands are homothetic and separable among import sources. Thus, within a market, trade patterns change only with relative price changes, and the elasticities of substitution between all

pairs of products (e.g., between United States and Canadian wheat) are identical and constant. These are strong restrictions on demand. In this paper we test these restrictions using data from the international cotton and wheat markets.

Three approaches are used in our empirical work. All three approaches test restrictions on a country's system of import demand equations for a product (cotton or wheat) from different sources. The maintained hypothesis is that imports of the product from different countries comprise a weakly separable group so that we are considering restrictions on the second stage of a two-stage budgeting process.

First, nonparametric methods (from Varian 1982, 1983) are used to test (*a*) whether the data are consistent with a stable system or well-behaved import demand equations and (*b*) whether Armington restrictions hold. This approach provides a complete test of the hypothesis in question with no additional assumptions concerning functional form (Varian 1983, p. 100). The principal drawback is the unknown power of the tests and the possibility of false rejections due to measurement error (Varian 1985, Chalfant and Alston).

Second, the Armington model is estimated and tested as a nested model defined by a set of parametric restrictions on a double-log import demand model incorporating the complete set of relative prices. This provides a direct test of the Armington model, but the drawback is that we are testing against an alternative that cannot be fully compatible with the adding-up restrictions from demand theory unless preferences are restricted to be homothetic (e.g., see Deaton and Muellbauer 1980b, pp. 17–18).

Our third approach follows Winters. The almost ideal demand system (AIDS) of Deaton and Muellbauer (1980a) is used to estimate the parameters of the import demand equations, and Armington restrictions are tested parametrically. As with the nonparametric approach, this approach tests necessary conditions for Armington restrictions to hold in a model in which other theoretical restrictions (symmetry and adding up) can be imposed; it does not test the complete set of restrictions (including functional forms for demand) that make up the Armington model. This approach avoids the drawbacks of the nonparametric approach (unknown power) and that of the direct approach with the ad hoc double-log model. However, it does involve the imposition of the AIDS functional form to be tested as a joint hypothesis with the Armington restrictions. That is, it tests whether import demand equations are separable and homothetic under the maintained hypothesis that they are of the AIDS form.

The three approaches are complementary. The alternate methods yield different results on particular restrictions, but we find that all three approaches comprehensively reject the Armington model. In every country each approach rejects the restrictions implied by the necessary conditions that the demand equations are both homothetic and separable. Thus, we conclude that the Armington trade model is inappropriate for cotton and wheat.

Two-Stage Theoretical Models

In general, a two-stage budgeting procedure assumes that consumers allocate their total expenditures in two stages (Deaton and Muellbauer 1980b). In the first stage, total expenditure is allocated over broad groups of goods, while in the second stage group expenditures are allocated over individual commodities. It is well known that weak separability of the direct utility function over broad groups of goods is a necessary and sufficient condition for the second stage of a two-stage budgeting procedure. However, weak separability imposes restrictions on consumer behavior. First, the marginal rate of substitution between two goods from the same group is independent of the consumption of goods in other groups. Second, the substitution effects between goods in different groups are limited. A price change of a commodity in one group affects the demand for a commodity in another group only through the group income effect. Third, separability implies a restrictive relationship between price and income effects. More specifically,

$$S_{ij} = \mu_{GH} \frac{\partial q_i}{\partial x} \cdot \frac{\partial q_j}{\partial x}, \tag{1}$$

where S_{ij} is the compensated cross-price effect, μ_{GH} is a constant depending on groups G and H, q_i and q_j are quantities of the ith and jth goods where i and j belong to different groups, and x is total expenditure.

In the context of a trade allocation model, the two-stage budgeting procedure can be explained as follows. In the first stage an importer's total imports of a particular commodity can be expressed as

$$M = M(Y, P, P_o, Z_1), \tag{2}$$

where M is total imports of the commodity (e.g., cotton), Y is the importer's national income; P is an index of the import price of cotton, P_o is a vector of the prices of all other goods, and Z_1 is a vector of other explanatory variables.

In the second stage, total imports of the commodity are divided up among the various suppliers of the product to yield

$$(3) \quad M_i = M_i(M, P_1, \ldots, P_n, Z_2), \qquad i = 1, \ldots, n,$$

where M_i represents the imports of cotton from country $i (i = 1, \ldots, n)$, P_j represents the import price of cotton supplied by the jth export nation and Z_2 is a vector of other exogenous variables.

How does Armington's model relate to the above two-stage budgeting procedure? The first two stages of Armington's framework are, in general, equivalent to those described above. That is, in the first stage the importer decides how much of a particular commodity to import [equation (2)]. In the second stage [equation (3)], given the total amount imported, the importer decides how much to import from each supplier. Thus, the implications of weak separability apply to the possible substitution effects among commodity groups. In addition, the Armington model uses a CES within-group specification. That is,

$$(4) \qquad w_i = b_i^{\sigma}\left(\frac{P_i}{P}\right)^{(1-\sigma)},$$

where w_i is the market share of imports from source i, b_i is a constant, P_i is the price of the commodity from the ith source, P is the import price index depending only on the within-group prices, and σ is the constant elasticity of substitution parameter. The CES specification implies weak separability between different import sources.[1]

Further, as is clear in the CES specification of equation (4), the Armington approach assumes homotheticity of the subutility or within-group utility functions. This implies that an importer's market shares are independent of group expenditures. Consequently, all expenditure elasticities within a group are equal and unitary and import market shares change only in response to relative price changes. Thus, the Armington framework implies that in the second stage (within-group allocations) market shares do not vary with expenditures and that different import sources are separable. To test the Armington model, we focus on the properties of the second stage and test the implied restrictions of homotheticity and separability.[2]

Data

Wheat imports were analyzed for five importing nations: China, Brazil, Egypt, U.S.S.R., and Japan. These countries accounted for approximately 51% of world wheat imports in 1984/85. Annual data for prices and trade flows were obtained from the International Wheat Council, *World Wheat Statistics*. Prices were FOB quotations, basis the exporting country.

The number of observations for each of the importing regions varied based on the availability of data and import developments for that particular country. For Japan, the estimation period covered the years 1960/61–1984/85. Brazil imports wheat from three sources: Argentina, Canada, and the United States. However, Brazil started importing wheat from Canada only in 1970/71, and therefore the estimation period for Brazil included the years 1970/71–1984/85. Egypt has three primary import sources: Australia, the EEC, and the United States. The data included the period 1971/72–1984/85. Imports of wheat by the Soviet Union varied dramatically over the years. The United States became a major source for the Soviets during the 1972/73 marketing year. Argentina, Australia, and the EEC became major wheat exporters to the Soviet Union during the early 1980s. Canada has been the only major foreign source of wheat supply to the Soviet Union since the 1960s, although the quantity imported varied considerably from year to year. The data used for the USSR included the period of 1972/73–1984/85. The same period of analysis was used for

[1] The Armington model imposes the CES functional form on equation (3). This is the typical approach followed by those who have estimated Armington models (e.g., Sarris; Grennes, Johnson, and Thursby; Abbott and Paarlberg; Figueroa and Webb), and it is addressed in this paper. Alternatively, others (e.g., Goddard) have modified the Armington model by using a different functional form. Goddard used a generalized Box-Cox functional form.

[2] These tests are conditional on some general assumptions. First, general separability assumptions are implicitly made in our approach. For example, both cotton and wheat are assumed weakly separable from all other commodities. In addition, leisure (labor supply decisions) is assumed separable from all other commodities, and our approach assumes intertemporal separability. In order to make consumer models tractable, these separability assumptions are frequently made. Finally, in every case, in order to make the models tractable, we abstract from the problem of aggregation over consumers and over different varieties of wheat and cotton. These general assumptions are usually made in applications of Armington models.

the People's Republic of China (PRC). Although Australia and Canada have been exporting wheat to the PRC since the 1960s, the United States did not export wheat to China until the early 1970s.

Cotton imports were analyzed for five leading importing nations: France, Italy, Japan, Taiwan, and Hong-Kong. In 1983/84 these five countries accounted for 37% of total cotton imports. Annual data for prices and trade flows were obtained from *World Cotton Statistics* published by the International Cotton Advisory Committee. Prices were c.i.f. Liverpool, England. As with wheat, the number of cotton observations varied for each importing region. For Italy, Hong Kong, and France, the time period studied was 1969/70–1983/84. Data for Japan and Taiwan were not available for 1983/84 and thus the equations were estimated using data from the 1969/70–1982/83 period.

Nonparametric Tests

The nonparametric approach to demand analysis uses the results of revealed preference analysis to derive algebraic conditions on demand functions (Varian 1983). These conditions are used to test for the compatibility of data with the existence of a utility function that "rationalizes the data," to use Varian's terminology. We can also test for the compatibility of data with the existence of a utility function that is homothetic, separable, or both homothetic and separable (as implied by the Armington model).

Varian spells out the relevant conditions succinctly. First, compatibility of the data with the existence of a utility function is necessary to conduct demand analysis and the required condition is that the data satisfy the generalized axiom of revealed preference (GARP). When this condition is not violated, the data are consistent with having been generated by the maximization of a utility function by a representative consumer.[3] Second, for data sets that satisfy GARP we can proceed to test compatibility of the data with restrictions on the utility function.

Satisfaction of the homothetic axiom or revealed preference (HARP) implies the existence of a homothetic utility function that rationalizes the data. Thus, to test the Armington restriction of homotheticity, we check whether the data satisfy HARP. A necessary condition for (weak) separability of a subgroup (of a group of goods that satisfies GARP) is that the subgroup also satisfies GARP. This is only a necessary condition, the sufficient conditions require that the data satisfy both GARP and the Afriat inequalities (Varian, p. 105); however, Barnett and Choi (also see Belongia and Chalfant) suggest that the use of the sufficient condition biases the nonparametric test towards rejection of separability. Thus, a conservative approach (erring in favor of the Armington model) is to use only the necessary conditions. Finally, for data that satisfy separability we can test for "homothetic separability," which holds when demands for goods within a separable group are homothetic.

Varian has developed computer programs to test these conditions. Our testing procedure uses these programs as follows. First, each data set is tested with GARP. Next, for data that satisfy GARP, we apply HARP to test for homotheticity, and we test for separability of each import source from the rest. Then, for any data set that satisfies all of these tests, the homothetic separability test is applied. Only sets of import data (prices and quantities by source) that satisfy all of these tests are completely compatible with the Armington assumptions.

The results of the nonparametric tests are summarized in table 1. First, most of the data sets satisfy GARP. The exceptions were Brazil's wheat imports, Hong Kong's cotton imports, and Taiwan's cotton imports. Of course, these violations might be due to measurement error. Following Chalfant and Alston, we checked to see how much of a measurement error would be needed to have caused the violations of GARP that we observed. In the case of Brazil's wheat, only a very small measurement error (about 1% of prices or quantities) in one year (1977/78) could have accounted for the violation. Similarly, a very small measurement error in 1983/84 may have caused the violation of GARP in the case of Hong Kong's cotton imports. In the case of Taiwan's cotton, larger measurement errors (say 5% in 1970/71 and in 1976/77) would be required to account for the violations.

To conduct other nonparametric tests using these data sets that violated GARP we eliminated one observation from the Brazilian wheat date (1977/78) and the Hong Kong cotton data (1977/78) and two observations from the Taiwanese cotton data (1970/71 and 1976/77). With these observations eliminated, the remaining data satisfy GARP. This procedure is justified if we believe the violations were caused by measure-

[3] Chalfant and Alston provide a more intuitive explanation of GARP which they use to test for structural change in demand for meats.

Table 1. Nonparametric Test Results

		Separability of Wheat Source Country[a]				
Importer	GARP[b]	Australia	Argentina	Canada	U.S.	EC
China	0	+[c]	+	+	+	
Brazil	2		+	−	−	
Egypt	0	+			−	+
USSR	0	−	−	+	+	+
Japan	0	+		+	+	

		Separability of Cotton Source Country								
Importer	GARP[b]	USSR	Egypt	Mexico	Turkey	Sudan	U.S.	Pakistan	Brazil	Nicaragua
Italy	0	−	−	−	+	+	+			
Hong Kong	2	−					+	+		
Taiwan	7			+			+		+	
France	0	+	+		+		−			
Japan	0	−	−				+			−

[a] The wheat sources are Australia, Argentina, Canada, the United States, and the European Community. The cotton sources are the Soviet Union (USSR), Egypt, Mexico, Turkey, Sudan, United States, Pakistan, Brazil, and Nicaragua.
[b] Entries under GARP denote the number of observations that violated the generalized axiom of revealed preference. Observations that caused the violations of GARP for those countries were deleted to allow tests for separability to be carried out. These were No. 7 (1977/78) for Brazil's wheat, No. 15 (1983/84) for Hong Kong's cotton, and No. 2 (1970/71) and No. 7 (1976/77) for Taiwan's cotton.
[c] Entries denoted "+" indicate that imports from that country are separable from imports from the alternative sources. Entries denoted "−" indicate that imports from that country are not separable from other sources. Blanks indicate that data were not available for that supplier.

ment errors. An alternative procedure would be to experiment with adjustments to the data until GARP was satisfied. To the extent that they satisfy GARP, we may treat imports as a separable group and proceed to test homotheticity and separability as within-group restrictions.[4]

The second test was for homotheticity. All ten of the data sets violated HARP at every observation. Thus, homotheticity is rejected for every system of import demand equations being studied.

Third, we tested for separability among import sources by excluding each source of imports in turn and testing whether the remaining sources make up a separable group by applying the necessary condition, GARP. In the case of China's wheat imports and Taiwan's cotton imports, separability was not rejected for any source country. However, for the other four wheat importers and the other four cotton importers, separability was rejected for one or more of the source countries. For example, for France's cotton imports, the United States was not separable from the other sources, although each of the other sources was separable from the group comprising the rest including the United States.

Finally, because all of the data violate HARP, the test for homothetic separability is redundant. None of the data satisfy the necessary conditions of the Armington model, homothetic separability.

Armington Estimates

Consider the following double-log specification of the "within-group" allocation of expenditures among n sources (i) of imports within a country:

$$\text{(5)} \quad \ln M_i = \alpha_i + \sum_{j=1}^{n} \gamma_{ij} \ln \frac{P_j}{P*} + \beta_i \ln \frac{M}{P*},$$

where M_i is the quantity imported from source i, P_j is the price of imports from source j, M is total expenditure on imports of the good from all sources, and $P*$ is Stone's (geometric) price index for imports of this good.

[4] The Armington model has been applied sometimes to a group comprising imports plus the domestically produced good (e.g., Grennes, Johnson, and Thursby). Alternatively, others have dealt only with import (excess) demand, without explicit treatment of domestic supply and demand (e.g., Sarris 1983). None of the importers studied in this paper produce significant amounts of cotton, but several of the wheat importing countries (especially the Soviet Union and China) produce most of the wheat that they consume. We are therefore assuming that domestic wheat is a differentiated product within the wheat group in these countries. The Armington restrictions imply that any subgroup is separable so that a test of Armington restrictions on a subgroup tests necessary conditions for the Armington model.

(6) $$\ln P^* = \sum_{k=1}^{n} w_k \ln P_k,$$

where w_k is the expenditure share of source k in total imports.[5]

This model is homogenous of degree zero in all prices and total expenditure. However, it is not possible in general to impose the theoretical restrictions of symmetry and adding up (e.g., see Deaton and Muellbauer 1980b). The Armington model of equation (4) is nested within this model under the restrictions that $\gamma_{ij} = 0 \ \forall \ j \neq i$ (i.e., weak separability means that only the own-price and group price are included), $\beta_i = 1 \ \forall \ i$ (demands are homothetic), and $\gamma_{ii} = \gamma_{jj} = -\sigma \ \forall \ i, j$ (i.e., equality of the own-price coefficients). Under these restrictions the system of demands does satisfy the theoretical restrictions of symmetry and adding up and $\gamma_{ii} = -\sigma$ is the elasticity of substitution for the system.

We estimated this model for the ten cotton or wheat importers and tested the Armington restrictions of separability ($\gamma_{ij} = 0 \ \forall \ j \neq i$), homotheticity ($\beta_i = 1 \ \forall \ i$), and equality of own-price coefficients ($\gamma_{ii} = \gamma_{jj} \ \forall \ i, j$). The estimates were obtained using iterative seemingly unrelated regressions (SUR) techniques and the parametric restrictions were tested using the likelihood ratio procedure for which the test statistic is

(7) $$2[\lambda_u - \lambda_r] \sim \chi^2(J),$$

where λ_u is the log-likelihood for the unrestricted model and λ_r is the log-likelihood for the model with J parametric restrictions imposed.[6]

The results of these estimations and tests are summarized in table 2. The Armington model seems to fit the data reasonably well, and the estimates are plausible with the exception of Egypt's wheat imports for which the elasticity of substitution is negative and significant.[7] Outcomes such as those in table 2 help to explain the popularity of the Armington approach. However, the Armington restrictions are comprehensively rejected with the chi-square tests. While homotheticity could not be rejected in four of the cases, separability, homothetic separability, and the Armington model were rejected in all ten cases. The full Armington restrictions were rejected in all ten cases when the models were corrected for first-order autocorrelation as well as in the seemingly unrelated regressions (SUR) estimation.

The drawback here is that the Armington model is rejected in favor of a model that we cannot require to satisfy the theoretical restrictions that we would like to impose (and which the nonparametric tests indicate can be imposed) on the data. These restrictions can be imposed in the AIDS model and separability and homotheticity restrictions can be tested subject to symmetry and adding up as maintained hypotheses.

AIDS Model Estimates

In an AIDS specification (Deaton and Muellbauer 1980a, b) of import demand, the budget share of imports from source i is given by

(8) $$w_i = \alpha_i + \sum_{j=1}^{n} \gamma_{ij} \ln p_j + \beta_i \ln(M/P), \quad i = 1, \ldots, n,$$

where the log of the price deflator is

(9) $$\ln P = \alpha_0 + \sum_k \alpha_k \ln p_k + \frac{1}{2} \sum_j \sum_k \gamma_{kj} \ln p_k \ln p_j,$$

where M is total expenditure on imports and p_j are prices of imports from source j. Adding up, homogeneity, and symmetry, respectively, require that

(10) $$\sum_i \alpha_i = 1, \sum_i \gamma_{ij} = 0 \text{ and } \sum_i \beta_i = 0; \quad \sum_j \gamma_{ij} = 0; \quad \text{and } \gamma_{ij} = \gamma_{ji}.$$

[5] Armington used a CES price index (see, also, Sarris 1983). However, he expressed the model in percentage change form which is equivalent to first differencing the logarithmic form. Taking first differences of equation (6) in the logarithms of prices (i.e., holding shares constant) results in the price index used by Armington.

[6] Autocorrelation was present in many of these models both with and without the Armington restrictions. While this does not lead to biased parameter estimates, it might lead to biased standard errors and biased test results. Given our nonparametric results, supporting the existence of a well-behaved static system of demand equations, it is probably appropriate to interpret this autocorrelation as evidence of model misspecification. In any event, our main results are not sensitive to autocorrelation corrections.

[7] This result could easily be rationalized as being caused by; for example, the extensive involvement of the Egyptian government in the wheat market. However, it does imply positive own-price elasticities of demand, a result that is not implied by the data alone because the data satisfy GARP.

Table 2. Armington Model Estimates for Wheat and Cotton

Commodity Importer[a]	Estimates[b] σ	R^2	χ^2 Statistics for Hypothesis Tests[c] S	H	H&S	Armington OLS	Auto[d]

[a] n is the number of import sources analyzed.
[b] These are SUR estimates from the model with the full set of Armington restrictions; t-values are in parentheses.
[c] These statistics refer to the restrictions $\gamma_{ij} = 0 \; \forall \, j \neq i$ (S = separability) and $\beta_i = 1 \; \forall \, i$ (H = homotheticity). H&S denotes the joint restriction of homothetic separability. "Armington" denotes the full set of Armington restrictions—homotheticity, separability, and equality ($\gamma_{ii} = \gamma_{ij} \; \forall \, i, j$). The degrees of freedom for the χ^2 equal the number of restrictions which are $n^2 - n$ (separability), n (homotheticity), n^2 (homothetic separability) and $n^2 + n - 1$ (Armington), where n is the number of import sources. * indicates significant at $p = 0.05$.
[d] Auto refers to results after correcting for first-order autocorrelation.

The aggregate price deflator in (9) can be approximated by Stone's index from equation (6).[8] Having made this substitution, the AIDS model is identical to the double-log specification in equation (5) except that expenditure shares replace logarithms of quantities as the dependent variables.

The test for homotheticity in the AIDS import share equations is equivalent to testing that all the β_i are zero. This implies that the import shares are independent of the total import level [see equation (8)]. To test for separability between import sources, we follow Winters and test whether the price from a particular import source contributes anything to the otherwise complete allocation model. This condition is a necessary consequence of separability. In general, one of the implications of separability over groups is that the within-group demand functions contain only prices of commodities within that group. Thus, for each import source we estimated an AIDS excluding it and then tested whether its price had any influence on the included import shares.[9]

The import demand models of equation (8) were estimated by iterative SUR techniques with symmetry and homogeneity restrictions imposed. Because of the adding-up condition, the contemporaneous covariance matrix is singular. Thus, the standard procedure of arbitrarily deleting an equation was employed. The iterative SUR estimators have the same asymptotic properties as maximum likelihood estimators. The

[8] For a discussion of the effects of this substitution on the properties of the subsequent estimators, see Blanciforti and Green. Green and Alston discuss implications for computation of elasticities.

[9] The spirit of this approach is directly analogous to that used in the nonparametric test for separability where we tested source-by-source whether the demand system was sensitive to the exclusion of a source. This is a test of a necessary condition for the Armington model's assumption that all sources are separable. It is not as strong as the condition that all sources be jointly separable which is required by the Armington model.

Table 3. AIDS Model Test Results for Japanese Wheat Imports

	Homotheticity	Separability	Homotheticity and Separability
Separable Country (i)	$\beta_k = 0$	$\delta_{ki} = 0$	$\delta_{ki} = 0; \beta_k = 0$
	(t, d.f. = 21)	(t, d.f. = 21)	(F, d.f. = 2,21)
Canada	−0.79	1.47	1.08
Australia	−6.94*	2.01	32.36*
U.S.	4.15*	−0.86	10.08*
Complete system	$\chi^2(2)$ = 37.23*		

Notes: The critical values of these statistics for $p = 0.05$ are $t_{21} = 2.08$, $F_{2,21} = 3.47$, $\chi^2_2 = 5.99$. Asterisk denotes significance at $p = 0.05$. The F-test statistic is calculated as:

$$\frac{\left[\dfrac{SSE_u - SSE_r}{J}\right]}{\left[\dfrac{SSE_u}{N-K}\right]} \sim F_{J,N-K},$$

where N is the number of observations, K is the number of parameters being estimated in the unrestricted model ($K = 5$), J is the number of restrictions being tested ($J = 2$), SSE_u and SSE_r are the sums of squares of residuals from the unrestricted and restricted models, respectively (e.g., see Judge et al.).

estimates are invariant to the equation deleted (Barten). Because the primary focus of the paper is to examine the usefulness of the Armington model, only the tests of separability and homotheticity are reported.

In half of the cases analyzed imports are supplied by only three sources (wheat into Brazil, Egypt, and Japan and cotton into Hong Kong and Taiwan). In these cases, when we exclude one source to test for separability and then delete a further equation for estimation because of the singular residual covariance matrix, a single equation model remains to be estimated by OLS. The single equation for the expenditure share of imports from source k represents the demand for imports from two sources (k and j) as a function of their prices and total expenditure on imports from the two sources. To test for separability of a third source (i), we use a t-test on the coefficient of the logarithm of the price of imports from that source (δ_{ki}) in the share equation for source k. To test homotheticity in the reduced model (including only two of three sources), we use a t-test on the coefficient of the logarithm of real expenditures in the share equation of source k (β_k). To test the joint restriction of separability of source i and homotheticity within the reduced model ($\delta_{ki} = 0$ and $\beta_k = 0$), we use a standard F-test. In all cases a system of equations was estimated to obtain unrestricted estimates, and to test for homotheticity alone, using iterative SUR. In these multiple equation models, we use likelihood ratio tests of the various parametric restrictions implied by homotheticity, separability, or homotheticity and separability. The test statistic is the chi-square defined in equation (7).

In the interests of brevity, not all of the test statistics are reported here. Instead, only the values for Japan are reported in detail and those for all other importers are tabulated and reported in summary form. All of the values for all countries are available from the authors. Japan was singled out because it is a major importer of both cotton and wheat. Tables 3 and 4 report the detailed Japanese test results for wheat and cotton, respectively. In every case, the first column of each table contains the import source which is being tested to determine whether it is separable from the other (included) import sources.

First, consider the homotheticity constraint. Initially we test this restriction alone without any separability restrictions on sources of imports within the group. The last entry in the second column of tables 3 and 4 reports the test statistic. For Japan the restriction is rejected for both wheat and cotton in the full model including all sources. Consider tables 5 and 6 which summarize results for all countries. In the last column of table 5 (for wheat) it can be seen that homotheticity is rejected at the 5% level of significance in two countries (Japan and USSR) and is not rejected for the others (China, Brazil, and Egypt) when all sources are included. The homotheticity constraint in cotton (see table 6) is not rejected in Taiwan and Italy but is rejected for the other three countries (Hong Kong, France, and Japan). The other entries under "homo-

Table 4. AIDS Model χ^2 Test Results for Japanese Cotton Imports

	Homotheticity	Separability	Homotheticity and Separability
Separable Country (i)	$\beta_k = 0\ \forall_k$	$\delta_{ki} = 0\ \forall_k$	$\delta_{ki} = 0$ and $\beta_k = 0\ \forall_k$
	(d.f. = 2)	(d.f. = 2)	(d.f. = 4)
Egypt	2.12	6.74*	19.60*
Nicaragua	8.76*	16.26*	17.84*
USSR	4.34	8.54*	20.28*
U.S.	5.14	11.34*	17.24*
Complete system	$\chi^2(3) = 10.70$*		

Notes: The critical values of the χ^2 distribution for $p = 0.05$ are 5.99 (d.f. = 2), 7.81 (d.f. = 3), and 9.49 (d.f. = 4); asterisk denotes significance at $p = 0.05$.

theticity" in tables 3, 4, 5, and 6 refer to tests for homotheticity within a reduced model where one of the sources has been excluded to test for separability. This restriction is rejected in two of three cases for Japanese wheat imports (table 3) and one of three cases for Japanese cotton imports (table 4). Looking at all of the countries studied, the restriction is rejected in twelve of eighteen cases for wheat (table 5) and five of twenty cases for cotton (table 6).

With respect to separability over import sources, consider the third column in tables 3 and 4. The coefficient, δ_{ki}, is the log price coefficient on the import source (i) being tested in the share equation for an included source (k). For each import source being tested, the AIDS was estimated excluding it and then tested to determine whether its price had any influence on the remaining import shares. For Japanese wheat imports (table 3), in all three cases, separability is not rejected. For wheat in total (table 5), separability is rejected in nine of eighteen cases, in four of the five countries. Turning to cotton, separability was comprehensively rejected for Japanese imports (table 4). As shown in table 6, overall, separability was rejected in sixteen of twenty cases, and at least once in each of the five countries.

Finally, in the last column of tables 3 and 4, homotheticity and separability were tested jointly. The joint test is the critical test of the Armington assumptions. In every importing country these joint constraints were rejected at least once. In tables 5 and 6 it is found that the joint con-

straints were rejected in fourteen of eighteen cases for wheat and in seventeen of twenty cases for cotton.

Synthesis of Results

Table 7 summarizes the results from the three alternative approaches to testing Armington restrictions on import demand equations for cotton and wheat. A plus indicates the restriction is not rejected, while a minus sign indicates the restriction is rejected. Homotheticity was rejected in ten of ten countries by the nonparametric method, six of ten countries in the double-log approach, and in five of ten countries using the AIDS model, twenty-one of thirty times in total. Separability was rejected in eight of ten countries using the nonparametric approach, all ten countries using the double-log model, and in nine of ten countries using the AIDS model. That is, the necessary conditions were rejected in twenty-seven out of thirty cases. These necessary conditions are relatively weak restrictions compared

Table 7. Summary of Nonparametric, Double-Log, and AIDS Model Test Results

		Homotheticity			Within-Group Separability			Homotheticity and Separability		
Commodity	Importer	1	2	3	1	2	3	1	2	3

	France	−	−	−	−	−	−	−	−	−
	Japan	−	+	−	−	−	−	−	−	−

Notes: (1) Nonparametric, (2) Double-log, (3) AIDS; a "+" indicates the restriction is not rejected, and "−" indicates the restriction is rejected (at $p = 0.05$ for parametric tests).

Table 8. Uncompensated Own-Price Elasticities of Demand for Imports of U.S. Cotton

	Elasticities at Sample Means[a]		
Importer	Armington Model[b]	Double-log Model	AIDS Model
France	−1.85*	−10.39*	−8.75
	(−4.22)	(−2.55)	
Japan	−1.12*	−3.98*	−2.92
	(−3.34)	(−2.30)	
Italy	−0.82*	−0.37	−2.80
	(−4.00)	(−0.19)	
Hong Kong	−2.35*	−7.75*	−3.82
	(−3.04)	(−4.44)	
Taiwan	−1.76*	−11.26*	−1.40
	(−6.85)	(−7.89)	

Notes: All elasticities are uncompensated "within-group" measures for second-stage allocations.
[a] t-values are in parentheses; for the Armington model these are t-values for $\hat{\sigma}$ which apply if shares are treated as exogenous.
[b] Armington elasticities computed according to $n_{ij} = -(1 - w_{ij})\sigma_i - w_{ij}$ where i denotes the importing country and j denotes U.S.

to the Armington separability restrictions. In the nonparametric and AIDS tests, we consider whether each source in turn is separable from the rest. The Armington model requires that all sources of imports are jointly separable. This restriction was rejected in all countries using the double-log model.

The joint test of homotheticity and separability is the critical test of the Armington model. On this criterion the results are quite unequivocal. With all three approaches and in each country, the Armington restrictions were comprehensively rejected.

Implications

Armington model estimates are commonly used in counterfactual policy simulations. In such contexts, the acid test might not be whether the Armington restrictions are rejected by the data but, rather, whether the resulting elasticity estimates are significantly biased. That is, how important is the finding that Armington restrictions do not hold in terms of the practical problems for which the estimates are being made?

A partial answer to this question is possible. In the context of the double-log model, the application of the Armington separability restriction, when it is inappropriate, amounts to omitting relevant explanatory variables. The omitted explanatory variables are prices of substitutes which are likely to be positively correlated with the own-price variable that is included. When the omitted prices are prices of substitutes (positive cross-elasticities), the own-price parameter estimate will be positively biased so that the own-price elasticities will be underestimated (i.e., less negative).[10] This argument is relatively straightforward in the context of the double-log model about which our reservations have already been expressed. Intuitively, it would seem reasonable to extrapolate to other functional forms, but that might not be appropriate. To illustrate the potential importance of these specification biases, own-price elasticities for imports of U.S. cotton in the five countries were computed using the three models (Armington, double-log, and AIDS). The results are in table 8.

The Armington estimates are mostly smaller than both the double-log and AIDS estimates. One exception is Italy's elasticity of demand for U.S. cotton where the double-log estimate is not statistically significant. With this exception the Armington model estimates are less elastic than the double-log estimates. This result is consistent with the argument above about the consequences of omitting relevant explanatory variables. The other exception is Taiwan's imports of U.S. cotton where the Armington model resulted in a demand elasticity slightly more elastic than that from the AIDS, although both were much less elastic than the estimate from the double-log model. If the AIDS model represented truth, we would say that the Armington model understates the true elasticities substantially (say 50%) in most cases. If the double-log estimates were correct, the biases are more important.

[10] This point was first suggested to us by Mike Wohlgenant (personal communication). Kmenta (pp. 443–44) proves the relevant arguments about the effect of omitting relevant explanatory variables.

Conclusions

This paper tested the assumptions of the Armington trade model in the context of the international cotton and wheat markets. The Armington model is comprehensively rejected with data from the five leading importing countries for each good, using three alternative testing approaches. This leads us to conclude that the Armington restrictions should not be applied as a matter of course in the analysis of import demand for these goods. By analogy, doubt is raised as to whether the Armington restrictions are appropriate for other goods and in other applications such as CGE modeling. At a minimum, where possible, commodity trade data should be tested for consistency with the restrictions, perhaps using tests like those used in this study. In general, it will be desirable and appropriate to use a less severely restrictive set of assumptions about demand relationships than those of the Armington model.

The main advantage of the Armington approach is its parsimony with respect to parameters to be estimated while retaining compatibility with demand theory. This advantage is often important in international trade studies where data are very limited, but it comes at a cost. When the restrictions are inappropriate, the parameters will be biased, possibly in important ways. When we use a parametrically more generous specification (such as the AIDS model), we lose the main advantage of the Armington model in exchange for reducing the risk of this specification bias. At the same time, as occurred in our estimates, risk of getting wrong signs is increased. Clearly, given the nonparametric results that support the existence of a well-behaved system of demands, the AIDS model can be a misspecified model, too. And, as with the Armington approach, data limitations restrict the options for specification searches to find the true model. Our tests comprehensively reject the Armington model for cotton and wheat. This leads to concern that similar conclusions may apply to other trade models in the literature based upon (untested) Armington restrictions.

The Elasticity of Export Demand for U.S. Cotton

Patricia A. Duffy, Michael K. Wohlgenant, and James W. Richardson

The conceptually relevant elasticity for policy analysis is the total export demand elasticity, which takes into account feedback effects of the U.S. price on other countries' prices. In this paper, a total export demand elasticity for U.S. cotton is estimated in an extended Armington framework. The results indicate that the export demand facing the United States is probably elastic; however, estimated total demand elasticities are considerably less elastic than the estimated direct demand elasticities, which do not account for feedback effects resulting from finite excess supply elasticities in the rest of the world.

Key words: cotton, export demand, total elasticity.

In designing agricultural policy, a knowledge of relevant elasticities is essential. Given the current economic climate characterized by volatile export markets and prices, the price elasticity of export demand has received considerable attention. Economists, however, have not reached a consensus about the magnitude of this parameter. In their review of studies of price elasticity of export demand for agricultural commodities, Gardiner and Dixit report seven estimates of the elasticity of export demand for U.S. cotton, ranging from −0.02 (Taylor and Collins) to −5.5 (Johnson). Because the policy recommendations based on the assumption of an elastic foreign demand could differ dramatically from those based on the assumption of inelastic foreign demand, further research in this area is warranted.

The objective of this paper is to develop estimates of the elasticity of foreign demand for U.S. cotton. The Armington approach was used to formulate models for estimation because it is simple to formulate, is a powerful method for modeling U.S. crop exports (Sarris 1981, Thompson), and had not been used extensively in modeling cotton trade. The study differs from previous works by extending the Armington framework to estimate "total" elasticities of demand, in which feedback effects of U.S. price on the price of other countries' cotton is taken into account. Results from this paper should be useful in estimating the elasticity of export demand for U.S. cotton and in demonstrating the importance of estimating "total" export demand elasticities.

Extended Armington Framework

Armington (1969a, b) developed a theory of international demand for commodities which are differentiated by kind and origin. In the Armington model, products are distinguished by kind of good (rice, cotton, wheat, etc.) and by place of origin. Thus, U.S. cotton and Mexican cotton would be two products in the cotton market.

The basic assumptions underlying the Armington framework are: (*a*) the marginal rate of substitution between any two products (e.g., U.S. cotton and Mexican cotton) is independent of the quantity of any other produce; (*b*) the elasticity of substitution between any two products in one market equals the elasticity of substitution between any two other cotton products in the same market; (*c*) the elasticity of substitu-

tion between any two products in a given market is constant.[1]

Armington's assumptions imply that the product import demand functions for a given good can be written as

$$(1)\qquad X_{ij}/X_i = b_{ij}^{\sigma}\,(P_{ij}/P_i)^{-\sigma},$$

where X_{ij} is the quantity of cotton from country j consumed by country i, X_i is total cotton consumed by country i, P_{ij} is the price of cotton from country j in country i, P_i is a price index of cotton in country i, and σ is the elasticity of substitution between any two products in a given market. Country i's total demand for cotton depends on the price index of cotton, P_i, the prices of other goods, and total expenditure. This structure of demand implies that the direct price elasticities of demand in country i have the form:

$$(2)\qquad N_{ijj} = -(1 - S_{ij}) * \sigma_i + S_{ij} * \eta_i,$$

$$(3)\qquad N_{ijk} = S_{ik} * (\sigma_i + \eta_i), \quad k \neq j,$$

where N_{ijk} is the elasticity of demand for cotton from country j with respect to the price of cotton from country k, in country i; S_{ij} is the expenditure share of cotton from country j in country i; and η_i is the overall elasticity of demand for cotton in country i. It is worth noting here that the Armington model assumptions about substitution elasticities are stringent in that all own- and cross-price relationships may be derived from a knowledge of the elasticity of substitution and overall elasticity of demand for the product.

Export demand facing a particular country supplying the good, say the United States, can be obtained by horizontally summing all product import demand curves facing this country. This specification implies that the own-price elasticity of demand for exports from the jth country (N_j) is the share-weighted sum of the own-price elasticities of demand in all importing countries. That is,

$$(4)\qquad N_j = \Sigma_i(X_{ij}/X_j)N_{ijj},$$

where N_{ijj} is defined by (2), and X_j is total exports from country $j(X_j = \Sigma_i X_{ij})$.

Equation (2) has been used by a number of researchers to compute demand elasticity for differentiated products (Babula; Grennes, Johnson, and Thursby; Johnson, Grennes, and Thursby). However, it is not a total demand response elasticity in the sense of Buse because prices of other products are assumed to remain constant in response to a change in the price of the product from the exporting country in question. For a good such as cotton, the United States accounts for a significant portion of total world trade, so other product prices would not be expected to remain unchanged when the U.S. price changes. In the context of the Armington framework, the total own-price elasticity of demand for exports from the jth country (N_j^*) would equal

$$(5)\qquad N_j^* = \Sigma_i(X_{ij}/X_j) * \{N_{ijj} + \Sigma_k N_{ijk} * (d\ln P_{ik}/d\ln P_{ij})\},$$

where N_{ijk} is defined by (3) and $k \neq j$. This specification assumes prices of other goods (e.g., corn, wheat, manufactures) and incomes in the importing countries are unaffected by changes in the export price of cotton from country j.

Conceptually, equation (5) shows that the demand curve facing country j can shift in response to a change in product price. If the excess supply curve of country k is upward sloping, then its border price will rise (fall) in response to an increase in the price of product j when the two products are substitutes (complements). Accordingly, the export demand curve facing country j will shift to the left so that the total demand response curve, *mutatis mutandis* demand curve, will be steeper than the *ceteris paribus* demand curve (Buse). Although the total elasticity of demand can easily be developed in the Armington framework, this point has received inadequate attention in the literature.

The price effect described here is conceptually distinct from the price transmission elasticity, which measures the response of internal domestic prices to changes in border prices.[2] Here, the focus is on the response of one country's border price to another country's border price. In this study, export demand elasticities for U.S. cotton will be estimated using both equations (4) and (5) so that the significance of indirect price effects can be ascertained.

Estimation Approach

Although the Armington approach can be used to develop market-share equations that are linear

[1] To relax the restrictive assumptions of the CES functional form, a constant ratio elasticity of substitution homoethetic (CRESH) functional form can be used. Artus and Rhomberg were the first to use this specification of the Armington model. The application of the CRESH model is substantially more complicated than application of the CES function, however, and there is no conclusive evidence for its superiority (Deppler).

[2] Following Bredhal, Myers, and Collins, elasticities of price transmission for cotton are assumed to be either 1 or 0, depending on whether centrally planned countries are assumed to be price responsive.

in the parameters and relatively easy to estimate, there has been little effort made to estimate σ directly. Both Armington; and Grennes, Johnson, and Thursby assumed σ was equal to three, and then used equation (2) to calculate the direct elasticity of import demand. Given the importance of σ in determining the elasticity of export demand, this parameter will be estimated directly in this study.

The Armington approach is particularly well suited to estimate the elasticity of import demand for a particular region because a system of market share demand equations for the region can be estimated with σ held equal across equations. The constraint would assure that the assumption of equal elasticity of substitution between product pairs would not be violated.

To estimate the demand elasticity facing an exporter, however, this type of approach would be impractical because the number of equations to estimate would be equal to $N * M$, where N is the number of importing regions and M is the number of exporters. Fortunately, failure to estimate the entire set of market share equations jointly for each importer does not lead to biased estimate of σ for the region, although the variances of the single-equation estimates would be expected to be greater than those from pooled estimates.

For this study, countries were grouped into five regions: (*a*) Western European nations (Europe), (*b*) Japan, (*c*) other Asian importers (Asia), (*d*) centrally planned nations, and (*e*) Canada. The Western European region is composed of Austria, Belgium, Denmark, Finland, Germany, Ireland, Italy, Netherlands, Norway, Sweden, Switzerland, United Kingdom, Yugoslavia, Spain, and Greece. The centrally planned nations are the USSR, the P.R.C., and Eastern Europe. The Asian group consists of Hong Kong, Phillippines, Thailand, Malaysia, Republic of China, and Indonesia.[3] Although Korea is a major importer of U.S. cotton, trade arrangements have been such that Korea imports virtually all of its cotton from the United States. These trade arrangements also make it difficult to discover the "true" price of U.S. cotton in the Korean market; hence, Korea was not included in the Asian group.

Time-series data for the years 1959–83 were used in the estimations. Actual adjustments may not be instantaneous, and as Ayuk and Ruppel have pointed out, export shipments often lag sales contracts. Accordingly, following Nerlove, the partial adjustment framework was used to estimate import demand equations. In this framework, equation (1) can be expressed as

$$\text{(6)} \quad \ln(MS^d_{ij}) = \sigma^*\ln(b_{ij}) - \sigma^*\ln(P_{ij}/P_i),$$

where MS^d_{ij} is desired market share of imports from country j into country i, and σ^* is the long-run elasticity of substitution. The relationship between the actual and the desired market share is expressed as

$$\text{(7)} \quad \ln(MS_{ij}(t)) - \ln(MS_{ij}(t-1)) = \delta\{\ln(MS^d_{ij}(t)) - \ln(MS_{ij}(t-1))\},$$

where the coefficient δ is the adjustment coefficient, and t indicates the time period. Substituting (7) into (6) and rearranging leads to

$$\text{(8)} \quad \ln(MS_{ij}(t)) = \delta\sigma^*\ln(b_{ij}) - \delta\sigma^* \ln(P_{ij}/P_i) + (1-\delta)\ln(MS_{ij}(t-1)),$$

where $\delta\sigma^* = \sigma$ is the short-run elasticity of substitution. Note that the formulas in (2) and (3) can still be used to derive short-run, own-, and cross-price elasticities of demand. A long-run elasticity can also be developed from (8) by dividing the short-run elasticity by $1 - \delta$. The short-run elasticities are of the most interest here given the constantly changing world economic environment.

To account for possible changes over time that are unrelated to relative prices, a trend can also be included in the estimates. This specification of trend is similar to that employed by Sarris (1983). In our study, we assumed that the intercept, b_{ij} was a function of time (T), so that

$$\text{(9)} \quad b_{ij} = A_{ij}T^{\beta}_{ij}.$$

Substituting (9) into (8) leads to the functional form to be estimated.

The adjustment framework used here is similar to those used by Sirhan and Johnson in their study of cotton demand in selected European markets and by Chambers and Just in their study of the export demand for wheat. The primary difference in the studies is that we adhere to the Armington formulation of the price ratio, and, consequently, the Armington method of calculating elasticities is appropriate.

All data were obtained from various issues of *Cotton World Statistics*. U.S. cotton price is the CIF Liverpool price of S.M. 1–1/16 inch cotton. The world average price is a trade-weighted average of the U.S. cotton price and prices of

[3] Market share equations for individual countries within a region were also developed. Aggregation did not appear to have a noticeable effect on the estimates of σ. Individual country estimates are not reported because of space considerations but are available from the authors on request.

Table 1. Market Shares of U.S. Cotton in Foreign Markets (1959–83)

	Europe	Japan	Other Asia	Canada	Centrally Planned
Constant	−0.508	−0.951	−0.457	−0.133	−2.988

comparable quality cotton growths from Mexico, Brazil, Iran, the USSR, Turkey, and Syria.

Estimated Market Share Equations

Generalized least squares (GLS) estimates of the market share equations are reported in table 1. The GLS procedure was used to correct for autocorrelation in equations that tested positively for it and to account for contemporaneous correlation across equations using Parks procedure. Because the estimated equations contain a lagged dependent variable, to correct for autocorrelation it was necessary to first create an instrumental variable for the lagged dependent variables following the method suggested by Wallis. (The first-pass OLS equations did not differ markedly from the final estimates.) R^2 values reported in the tables are from prior stage estimates that have not yet been corrected for contemporaneous correlation.

Estimates of the elasticity of substitution range from a low of 2.16 in the Asian region to a high of 18.91 in the centrally planned region.[4] A lagged price ratio was used in the equation for the centrally planned nations. When current prices were used, the estimate of sigma was statistically insignificant at the 10% level.[5] Although the centrally planned nations, by definition, do not operate under the assumptions inherent in neoclassical microeconomic theory, it is reasonable to assume that they would be sensitive to the relative prices of the various cotton products once the import levels were determined. The appropriateness of including the centrally planned nations as import price sensitive should be explored further in future research.

In table 2, elasticity estimates are presented for three assumptions about the overall elasticity of demand for cotton (η_t). First, an upper bound of 0 (perfectly inelastic) and a lower bound of −1 (unitary elasticity) were assumed. Both intuition and empirical evidence suggest that total short-run demand for cotton fiber is inelastic. Spinning technology is largely fixed in the short run, limiting the substitution of other fibers (Jones-Russell). Additionally, the cost share of raw cotton in finished textile products is small (Wohlgenant). Total elasticities of demand, calculated from Babula's first-stage demand equations, ranged from −0.12 (Korea) to −0.257 (Japan). Monke and Taylor estimated a pooled short-run elasticity of demand of −0.24 for major cotton-consuming nations. Given the preponderance of evidence, we assumed first-stage demand to be inelastic, and 0 and −1 were chosen as probable bounds on the total elasticity. Two estimates of the elasticity of import demand for U.S. cotton were calculated by setting total elasticity equal to each of these boundary values. Finally, a third estimate of the export demand elasticity was calculated using the Monke and Taylor estimate of total demand elasticity (−0.24) in all regions.

Using equation (2) in equation (4), the direct elasticity of demand for U.S. exports, N_{us}, is expressed as

$$(10)\quad N_{us} = \Sigma_i\, x^i_{us}/X_{us}\,\{-\sigma^i(1 - S^i_{us}) + \eta_t S^i_{us}\},$$

where x^i_{us} is U.S. imports into country i, η_t is the total elasticity of demand for cotton (as-

[4] The five regional equations were also estimated without the adjustment framework. In four of the five regions, the absolute value of the price-ratio parameter increased, but only in Europe did it increase by a large percentage (−12.24 in the unadjusted model). The Japanese parameter decreased slightly in absolute value. R^2 values fell considerably in most cases.

[5] Ayuk and Ruppel found that the lag between contract and shipment can have a significant effect on estimates of the own-price effect. These countries may have a longer than average delay before shipments are made, causing the lagged price ratio to be more appropriate. This information is not in the general public domain, however, so this hypothesis would be difficult to test.

Table 2. Calculation of Elasticities from Aggregating into Regions

Region	Average U.S. Market Share 1977–82	σ	Average % all U.S. Exports 1977–82	$\eta_t = 0$	Elasticity $\eta_t = -.24$	$\eta_t = -1$
Europe[a]	.153	8.39	.110	−7.106	−7.143	−7.259
Asia[b]	.480	2.72	.266	−1.123	−1.238	−1.603
Japan	.426	3.12	.211	−1.790	−1.892	−2.216
Canada	.902	4.90	.035	−0.480	−0.696	−1.382
Centrally Planned Nations[c]	.239	18.91	.172	−14.391	−14.448	−14.630
1) Weighted average without Centrally Planned Nations			.582	−1.42	−1.50	−1.68
2) Weighted average with Centrally Planned Nations			.754[d]	−3.90	−3.97	−4.19

[a] Austria, Belgium, Denmark, Finland, Germany, Ireland, Italy, Netherlands, Norway, Sweden, Switzerland, U.K., Yugoslavia, Spain, and Greece.
[b] Japan, Hong Kong, Philippines, Thailand, Malaysia, Republic of China, and Indonesia.
[c] USSR, Eastern Europe, and People's Republic of China.
[d] Republic of Korea accounted for nearly all remaining cotton exports from U.S.

sumed equal across regions), X_{us} is total U.S. exports, and σ^i is the elasticity of substitution for cotton products in the ith region or country. Because the price of U.S. cotton historically has been quite close to the average price of cotton, the sales shares in equation (10) are approximated by quantity shares.

With the exception of Canada, there are no dramatic changes in N_{us} under the alternative assumption. When the centrally planned nations are excluded from the trade-weighted elasticity (i.e., when the elasticity of price transmission is set to zero for these countries), the upper bound estimate is -1.42 ($\eta_t = 0$) and the lower bound estimate is -1.68 ($\eta_t = -1$). Assuming an elasticity of price transmissions of 1.00 for the centrally planned nations brings the estimates of the trade-weighted elasticities to -3.90 ($\eta_t = 0$) and -4.19 ($\eta_t = -1$). Using Monke and Taylor's estimate of total demand elasticity results in a trade-weighted estimates of -1.50 for the assumption of nonprice-responsive centrally planned nations and -3.97 for the assumption of price-responsive centrally planned nations.

The estimates without the centrally planned countries are reasonably close to those calculated by Wohlgenant, and the estimates with the centrally planned nations are close to Johnson's calculated elasticity, which included these countries. It is clear from these calculations that relatively large changes in the overall elasticity of demand have only a small effect on the elasticity of demand for U.S. cotton. The inclusion or exclusion of the centrally planned nations is important, however.

Estimates of Total Export Demand Elasticities

The estimates developed in the preceding section are valid only if the price of cotton from other exporters will not change in response to a change in U.S. price. This condition implies a perfectly elastic export supply, an assumption that seems unrealistic. By its nature, the Armington model lends itself easily to the development of a far less restrictive model in which finite elasticities of export supply can be incorporated.

A simple static equilibrium model can be used to determine the change in competing product prices with respect to a change in the U.S. price. Let q_1 represent U.S. imports and q_2 represent imports from all other countries. Totally differentiating demand and supply yields

(11) $$d\ln q_1 = e_{11}\, d\ln P_1 + e_{12}\, d\ln P_2$$
(import demand for U.S. cotton)

(12) $$d\ln q_2 = e_{21}\, d\ln P_1 + e_{22}\, d\ln P_2$$
(import demand for other cotton)

(13) $$d\ln q_2 = E_s d\ln P_2$$
(export supply from ROW),

where e_{11} and e_{22} are direct own-price elasticities of demand for q_1 and q_2, respectively, e_{12} and e_{21} are the direct cross-price elasticities, E_s is the elasticity of export supply from competing suppliers, and ROW means rest of the world.

From (12) and (13), we obtain the impact of the U.S. border price on other countries' prices as

(14) $$d\ln P_2/d\ln P_1 = e_{21}/(E_s - e_{22}).$$

Substituting (14) into (11) and solving for $d\ln q_1/d\ln P_1$ yields the simplified expression for total demand response elasticity in (5) as

$$(15)\quad d\ln q_1/d\ln P_1 = e_{11} + e_{12} * e_{21}/(E_s - e_{22}).$$

For this aggregate model, consisting of the United States and the rest of the world, the counterparts to (2) and (3) are

$$e_{11} = -\sigma(1 - S_{us}) + \eta_t S_{us}$$

$$e_{12} = \sigma(1 - S_{us}) + \eta_t(1 - S_{us})$$

$$e_{21} = \sigma S_{us} + \eta_t S_{us}$$

$$e_{22} = -\sigma S_{us} + \eta_t(1 - S_{us}),$$

where σ is the aggregate elasticity of substitution between the United States and the ROW. Because regional estimates were used in these calculations, world-wide elasticities were derived by summing trade-weighted regional estimates. The trade weights are the percentages of total competing exports sent to each importing region.

Using regional estimates of σ leads to estimates of 2.22 for e_{21} and -2.46 for e_{22} when the centrally planned nations are assumed price responsive. If the centrally planned nations are considered nonresponsive, the estimates are .796 for e_{21} and $-.959$ for e_{22}.

An estimate of E_s can be obtained either by direct estimation or by using the excess supply specifications:

$$(16)\quad E_s = \Sigma_i e_{si}(Q_{xi}/Q_{si}) - \eta_{di}(Q_{xi}/Q_{di}),$$

where e_{si} is the domestic supply elasticity, Q_{xi} is quantity of exports from the *i*th country or region, Q_{si} is total supply in country i, N_{di} is domestic demand elasticity, and Q_{di} is domestic use. Using e_{si} of .38 and N_{di} of $-.24$ (Monke and Taylor) for the major price-responsive competing exporters and domestic elasticities of zero for the USSR yields an excess supply elasticity for U.S. competitors in the cotton market of 1.11.[6]

Using these elasticity estimates leads to a value for equation (14) of .62 when the centrally planned importing region is assumed price responsive, and .38 when the centrally planned importing region is assumed nonprice responsive. These, in turn, lead to estimates of the total elasticity of export demand of -1.62 (price-responsive centrally planned region) and -0.97 (non-price-responsive centrally planned region).

[6] The competing price-responsive exporters are Syria, Australia, Turkey, Israel, India, and the cotton-producing countries of South America, Central America, and Africa.

Conclusions

In this study, the usual Armington framework was extended to account for finite elasticities of export supply from U.S. competitors. The resulting "total" elasticities are more realistic for evaluating the effects of U.S. policy changes. Accounting for feedback effects of the U.S. price on other countries' cotton prices had a significant impact on the estimated export demand elasticity. Trade-weighted elasticities decline from about -4 to -1.6 when centrally planned importers are assumed price responsive, and from about -1.5 to -1.0 when centrally planned importers are assumed nonprice responsive.

Based on this work and the existing literature, it is highly probable that the direct elasticity of export demand for U.S. cotton is elastic. However, the total elasticity is considerably less elastic. Policy analysts should be aware that evaluating policy changes using only the direct elasticity may yield misleading results. For commodities such as cotton, for which the United States accounts for a large share of total world trade, the conceptually relevant elasticity for policy analysis is the total export demand elasticity; it takes into account the feedback effects of the U.S. price on other countries' prices.

Alternative Estimates of Fed Beef Supply Response to Risk

Frances Antonovitz and Richard Green

Supply response models for fed beef incorporating risk by including both the mean and variance of output price are developed, estimated, and compared. Six different estimates of the mean and variance are obtained from futures prices; ARIMA processes; and naive, adaptive, and rational expectations models. Empirical estimates are compared using nonnested testing procedures and indicate that the choice of the expectations model significantly influences elasticity estimates and whether supply response is positive or negative. Empirical evidence does not support any one model in particular, suggesting that expectations are heterogenous rather than homogenous.

Key words: fed cattle, nonnested hypothesis testing, price expectations, risk, supply response.

Most agricultural production is characterized by a lag between the time input decisions are made and the time output actually reaches the market. As a result, supply response functions are based on the hypothesis that quantity produced depends on known input prices and producers' expectations of output price. Expectations frequently have been modeled based solely on past prices. Examples include naive expectations, adaptive expectations (extensively reviewed by Askari and Cummings), and autoregressive integrated moving-average (ARIMA) schemes. Gardner as well as others have used futures prices to estimate producers' expected prices, although Chavas, Pope, and Kao found that futures prices are not good proxies for producers' expectations in the presence of government programs. Furthermore, Muth's concept of rational expectations has also been empirically tested for agricultural commodities by Goodwin and Sheffrin, and Shonkwiler and Emerson. However, some authors have argued that ARIMA specifications are essentially equivalent to rational expectations and are empirically easier to implement (e.g., Feige and Pearce; Nerlove, Grether, and Carvalho). Others (e.g., Orazem and Miranowski, Shonkwiler and Hinckley) use futures prices as rational expectations.

Hence, there is diversity in the literature about the interpretation and estimation of rational expectations. In addition, evidence has supported heterogenous rather than homogenous expectations. That is, because market participants may form their expectations in different ways, the aggregate of these expectations is better characterized by a weighted average of a number of models rather than simply one model. Frankel and Froot find this to be the case for exchange rate expectations, and Shonkwiler and Hinckley for feeder cattle.

Most supply response models have focused on the mean of producers' subjective distribution (or the price expectation), excluding the variance and higher moments from the model. A few authors (Behrman; Just 1974, 1977; Traill; Lin; Ryan; Antonovitz and Roe 1986a, b) have introduced risk into their supply response functions, although each of these authors examines only one model of price expectations in the analysis. All of these studies find that the risk variables are important to some extent. Hence, empirical evidence suggests that risk should not be neglected in supply response, but exactly which model best reflects this risk component has not been the focus of any study.

The purpose of this paper is to develop, estimate, and compare a number of supply response models for fed beef that incorporate the

mean and variance of the distribution of output price. Six different estimates of the mean and variance are obtained from the following models: futures price; ARIMA processes; and naive, adaptive, and rational expectations models. Empirical estimates of each are presented and compared using nonnested testing procedures.

The work in this paper makes a number of important contributions. The derivation and estimation of a supply response model including rational expectations of both the mean and variance are novel. In addition, the empirical results indicate that the choice of the expectations model is critical for fed beef and, hence, may be important for other commodities as well. Either a positive or a negative supply response may be observed depending on the choice of the expectations model, and elasticity estimates with respect to the mean and the variance may also be quite different.

The Model

Supply response for the United States fed cattle market will be modeled by specifying quantity as a linear function of input prices and the mean, variance, and higher moments of producers' expectations of output price. A theoretical justification for this model is provided by Roe and Antonovitz (1986a).

When feeder cattle are purchased by the feedlot operator, the sale price five to eight months later is not known.[1] Although the sale of futures contracts by feedlot operators could reduce this price risk, Antonovitz and Roe estimate that less than 2% of all cattle marketed are hedged in the futures market; thus, hedging is excluded from the analysis. Most enterprise costs are comprised of direct costs, especially feeder cattle and feed. Hence, feeder cattle and corn prices, which are assumed to be known when the feeder cattle are purchased, are the relevant input prices in the supply equation.[2] Any number of moments of producers' subjective distribution of fed cattle price could be used in specifying supply response; however, only the mean and variance are considered in this study. A bimonthly model (i.e., combining every two months) is formulated because it lends itself to estimation of the price expectations model.[3] Because fed cattle production has a distinct seasonal pattern with the heaviest placements in the fall months, bimonthly dummy variables were also included in the model. The aggregate supply function for fed cattle can be specified as

$$(1) \quad QCAT_t = \beta_o + \sum_{i=1}^{5} \beta_i S_{it} + \beta_6 PCN_{t-r} + \beta_7 PF_{t-r} + \beta_8 P_t^* + \beta_9 \sigma_t^* + \epsilon_t,$$

where S_{it} are bimonthly dummy variables to reflect seasonality; $QCAT_t$ is quantity of fed cattle marketed in bimonth t, total liveweight in million pounds; PCN_{t-r} is the average price of corn three to four bimonths prior to t, dollars per bushel; PF_{t-r} is the average price of feeder cattle three to four months prior to t, dollars per hundredweight; P_t^* is the fed cattle price expected in bimonth t formulated three to four bimonths prior to t, dollars per hundredweight; σ_t^* is the variance of fed cattle price expected in bimonth t formulated three to four bimonths prior to t, dollars squared per hundredweight squared; and ϵ_t is the error in bimonth t.

Seventy-four bimonthly observations from 1972 through the second bimonth of 1984 were used to estimate the functions. Supply was represented by fed cattle marketings in seven major cattle feeding states. Corn price was expressed as the price received by farmers in Iowa averaged three to four bimonths prior to t. Feeder cattle price was determined by averaging 400–500 pound (four bimonths prior to t) and 600–700 pound (three bimonths prior to t) choice feeder steer prices in Kansas City. Both input prices were specified in 1967 dollars by dividing by the index of prices paid by farmers for production items, interest, taxes, and wages. All data were obtained from U.S. Department of Agriculture (USDA) sources.

Price Expectations Models

The models used to estimate the mean and variance of the price distributions will be discussed in this section.

[1] The five- to eight-month lag reflects the feeding periods for both the midwestern and western regions as indicated by Gee, Van Arsdall, and Gustafson.

[2] Hurt and Garcia find that uncertainty in input prices also significantly influences sow farrowings. Although uncertainty in corn price during the feeding period may affect supply response, we have chosen, as do most other authors, to focus on output price uncertainty. Soybean price was also included in the supply response to reflect an additional input cost. However, it was statistically insignificant and, hence, omitted from the supply response equations.

[3] A bimonthly model was chosen because it was most consistent with the futures market data. Contract delivery dates for live cattle occur every other month starting in February. Hence, each bimonth would reflect only one futures contract delivery date.

Naive Expectations

Expectations are naive if the producer simply uses the output price at the time inputs are purchased as the expected sale price. These expectations were estimated by deflating average monthly price received by U.S. farmers for beef cattle to 1967 dollars by the monthly consumer price index. (The bimonthly deflated fed cattle price calculated from this series is denoted by $PCAT_t$.) The mean and variance of the monthly prices three to four bimonths (or five to eight months) prior to bimonth t were used to estimate P_t^* and σ_t^*; they are denoted by PNM_t^* and PNV_t^*, respectively. For example, to estimate the naive expectations variables for the first bimonth of 1972, the mean and variance of monthly prices from May through September of 1971 were calculated. For the second bimonth of 1972, monthly observations from July through November of 1971 were used, etc.

ARIMA Forecasts

Another method using only past prices to estimate price expectations is the ARIMA model. The bimonthly deflated fed beef price series, $PCAT_t$, between 1961 and 1984 was identified to most closely follow either an ARIMA (2,1,0) or an ARIMA (1,1,1) process. Different forecasts of the mean and variance were obtained for each model. A moving ARIMA model using ten years of the $PCAT_t$ data series was used to find three- and four-bimonth-ahead forecasts and their respective mean-square forecasting errors for each of the time periods between 1972 and 1984. For example, the mean and variance for the first bimonth of 1972 were estimated as follows. A three-step-ahead forecast and the corresponding mean-square forecasting error were obtained for the ARIMA model using data between the fifth bimonth of 1961 and the fourth bimonth of 1971. A four-step-ahead forecast and the mean-square forecasting error were also obtained using bimonthly price data between the fourth bimonth of 1961 and the third bimonth of 1971. The average of the three- and four-step-ahead forecasts were used to approximate the mean, and the average of the mean-square forecasting errors formed the estimate of the variance. Estimates of the mean and variance for the second bimonth of 1972 were obtained from three-bimonth-ahead forecasts (using data from 1961–66 to 1971–75) and four-bimonth-ahead forecasts (using data from 1961–65 to 1971–74), and so forth.

Futures Prices

Producers also may use the price of the futures contract maturing when output will be marketed as their expectation of output price. The price expectations based on futures prices were estimated from data in the *Chicago Mercantile Exchange Yearbook*. For the live cattle futures contract maturing in each bimonth from 1972 through 1984, thirteen daily deflated futures prices were selected from the three to four bimonths prior to contract maturity.

More specifically, the mean and variance for the first bimonth of 1972 were calculated as follows. The February 1972 futures contract was used because it matured during the first bimonth of the year. Thirteen daily opening prices of this contract were selected from the previous three to four bimonths (i.e., May, June, July, and August of 1971). The daily prices selected from May 1971 were deflated to 1967 dollars by the monthly consumer price index for May 1971, those selected from June were deflated by the consumer price index for the month of June, etc. The mean and variance of these thirteen prices were computed. For the second bimonth of 1972, thirteen daily opening prices of the April 1972 contract were selected from March through June of 1971, etc. However, the price expectations computed from the futures data may not precisely correspond with the $PCAT_t$ data series because futures prices reflect a specific quality of cattle for particular delivery points while the $PCAT_t$ series is based on national average prices.

Adaptive Expectations

The adaptive expectations model (Nerlove) posits that producers revise their expectations in proportion to the error associated with the previous level of expectations:

$$(2) \quad P_t^* - P_{t-r}^* = \lambda(P_{t-r} - P_{t-r}^*) \quad 0 < \lambda \leq 1$$

$$(3) \quad \sigma_t^* - \sigma_{t-r}^* = \gamma(\sigma_{t-r} - \sigma_{t-r}^*) \quad 0 < \gamma \leq 1.$$

Equation (2) can be restated using the lag operator L as

$$(1 - (1 - \lambda)L^r)P_t^* = \lambda P_{t-r}$$

and solving for P_t^*:

$$(4) \quad P_t^* = \frac{\lambda}{1 - (1 - \lambda)L^r} P_{t-r}.$$

Similarly, an expression can be found for σ_t^*:

$$\sigma_t^* = \frac{\gamma}{1 - (1 - \gamma)L^r} \sigma_{t-r}. \tag{5}$$

Because producers purchase feeder cattle three to four bimonths prior to marketing, the naive expectations of mean and variance defined earlier, PNM_{t-r} and PNV_{t-r}, are used to estimate the moments of fed cattle price in previous periods, P_{t-r} and σ_{t-r}. The supply response function can be obtained by substituting equations (4) and (5) into (1) and multiplying through by the expressions containing lag operators in the denominators.

$$AQCAT_t = \beta_o^a + \sum_{i=1}^{5} \beta_i^a S_{it} + \beta_6 APCN_{t-r} + \beta_7 APF_{t-r} + \beta_8 AP_t^* + \beta_9 A\sigma_t^* + V_t, \tag{6}$$

where

$$AQCAT_t = QCAT_t - (2 - \lambda - \gamma)QCAT_{t-r} + (1 - \lambda)(1 - \gamma)QCAT_{t-2r}$$

$$APCN_{t-r} = PCN_{t-r} - (2 - \lambda - \gamma)PCN_{t-2r} + (1 - \lambda)(1 - \gamma)PCN_{t-3r}$$

$$APF_{t-r} = PF_{t-r} - (2 - \lambda - \gamma)PF_{t-2r} + (1 - \lambda)(1 - \gamma)PF_{t-3r}$$

$$AP_t^* = \lambda PNM_{t-r} - \lambda(1 - \gamma)PNM_{t-2r}$$

$$A\sigma_t^* = \gamma PNV_{t-r} - \gamma(1 - \lambda)PNV_{t-2r}$$

$$V_t = \epsilon_t - (2 - \lambda - \gamma)\epsilon_{t-r} + (1 - \lambda)(1 - \gamma)\epsilon_{t-2r}.$$

The adaptive means and variances, AP_t^* and $A\sigma_t^*$, are estimated separately by using results from the naive expectations model. Just (1977), however, points out that simultaneously estimating the means and variances within the supply response function would yield more efficient estimates of the coefficients.

Rational Expectations

The Muth rational expectations hypothesis maintains that producers act as if they were solving the market supply and demand system when forming their expectations. The supply equation will be identical to the one defined earlier

$$QCAT_t = a_o + \sum_{i=1}^{5} a_i S_{it} + bP_t^* + c\sigma_t^* + dPCN_{t-r} + ePF_{t-r} + \epsilon_t. \tag{7}$$

The farm-level demand equation is specified in price dependent form to reflect that quantity is predetermined in period t and is given by

$$PCAT_t = f + gQCAT_t + hI_t + iY_t + U_t, \tag{8}$$

where Y_t is per capita disposable income in bimonth t, I_t is a farm-level index of other meats in bimonth t and equals

$$\sum_j P_t^j Q_t^j \Big/ \left(\sum_j P_t^j Q_t^j + PCAT_t \cdot QCAT_t \right),$$

where P^j and Q^j are the farm-level prices and quantities of chicken and pork,[4] and U_t is error in bimonth t.

Per capita disposable income was obtained from USDA sources and deflated to 1967 dollars by the consumer price index. The farm-level index of other meats was calculated from the following USDA data: young chicken slaughter, commercial hog slaughter, and average prices received by farmers for broilers and hogs.

The rational expectation of the mean of fed cattle price was found by first substituting equation (7) into (8).

$$PCAT_t = f + g\left(a_o + \sum_{i=1}^{5} a_i S_{it} + bP_t^* + c\sigma_t^* + dPCN_{t-r} + ePF_{t-r} + \epsilon_t\right) + hI_t + iY_t + U_t. \tag{9}$$

Taking expectations of both sides of equation (9), assuming that expectations are rational [i.e., $E(PCAT_t) = P_t^*$], and solving for P_t^* we obtain

$$P_t^* = \frac{f + g\left(a_o + \sum_{i=1}^{5} a_i S_{it}\right) + gc\sigma_t^* + gdPCN_{t-r} + gePF_{t-r} + hI_t^* + iY_t^*}{1 - gb}, \tag{10}$$

[4] This is the same model as the one specified by Antonovitz and Roe. However, they did not estimate the system simultaneously because producers were not assumed to have rational expectations. A reviewer pointed out that a failure to account for structural changes in the demand for meats may lead to rejection of the rational expectations hypothesis for the wrong reason. However, Chalfant and Alston found that specification errors in econometric demand studies can account for findings of taste changes. Thus, the problem is essentially one of realizing that specification of the demand function influences the expressions of and subsequent tests of the rational expectations hypothesis.

where I_t^* and Y_t^* are the expectations of the income and index variables formulated by producers when inputs are purchased. To find the rational expectation of the variance of fed cattle price, the expression for P_t^* in equation (10) is substituted into (9):

$$(11)\quad PCAT_t = f + g\left(a_o + \sum_{i=1}^{5} a_i S_{it}\right) + gb\left[f + g\left(a_o + \sum_{i=1}^{5} a_i S_{it}\right) + gc\sigma_t^* + gdPCN_{t-r} + gePF_{t-r} + hI_t^* + iY_t^*\right]\Big/(1 - gb) + gc\sigma_t^* + gdPCN_{t-r} + gePF_{t-r} + g\epsilon_t + hI_t + iY_t + U_t.$$

If P_t^* is subtracted from the left-hand side of equation (11) and its equivalent from equation (10) is subtracted from the right-hand side of (11), the resulting expression is

$$(12)\quad P_t - P_t^* = h(I_t - I_t^*) + i(Y_t - Y_t^*) + g\epsilon_t + U_t.$$

Squaring both sides of equation (12), taking the expected value, and assuming that the exogenous variables are uncorrelated with the error terms, we obtain

$$(13)\quad E(PCAT_t - P_t^*)^2 = \sigma_t^* = h^2IV_t^* + i^2YV_t^* + 2hiCOV_t^* + g^2E(\epsilon_t^2) + E(U_t^2) + 2gE(U_t\epsilon_t),$$

where IV_t^* and YV_t^* are the expected variances of index and income for bimonth t, and COV_t^* is the expected covariance between income and index for bimonth t, with all expectations formulated when inputs are purchased.

If the expressions for the rational expectations mean and variance, equations (10) and (13), are substituted back into supply equation (7), the demand and supply system can be written as[5]

$$(14)\quad PCAT_t = f + gQCAT_t + hI_t + iY_t + U_t, \text{ and}$$

$$(15)\quad QCAT_t = \frac{a + bf}{1 - gb} + \frac{\sum_{i=1}^{5} a_i S_{it}}{1 - gb} + \frac{d}{1 - gb}PCN_{t-r} + \frac{e}{1 - gb}PF_{t-r} + \frac{ch^2}{1 - gb}IV_t^* + \frac{ci^2}{1 - gb}YV_t^* + \frac{bh}{1 - gb}I_t^* + \frac{bi}{1 - gb}Y_t^* + \frac{2hic}{1 - gb}COV_t^* + \frac{c}{1 - gb}E(U_t^2) + \frac{cg^2}{1 - gb}E(\epsilon_t^2) + \frac{2cg}{1 - gb}E(U_t\epsilon_t) + \epsilon_t.$$

Wallis suggests that the expected values of the exogenous variables, I_t^* and Y_t^*, can be estimated by ARIMA models. Hence, a procedure similar to that employed to obtain expectations of fed cattle price from ARIMA models was used. Using bimonthly data between 1961 and 1984, deflated per capita disposable income was identified to most closely follow an ARIMA (1,1,0) process; the index variable followed an ARIMA (1,2,1) process. Moving ARIMA models, estimated with ten years of data to find three- and four-bimonth-ahead forecasts and mean square forecasting errors, were again used to calculate I_t^*, Y_t^*, IV_t^*, and YV_t^*. The covariance variable was approximated by first determining a simple moving covariance between I_t and Y_t using previous ten years of data. The average of the covariances three and four bimonths prior to t formed the estimate of COV_t^*.

Empirical Results

Prior to presenting the empirical results, it is necessary to consider the effects of using generated or constructed variables (for anticipated prices and variances) in the estimations. If producers respond to realizations from stochastic processes that generate output prices and variances, then we are in a stochastic regressors world. This interpretation is plausible because producers have to make decisions based on actual forecasts of future unknown output prices and variances. This view is also consistent with the methods used to generate price and variance

[5] For estimation purposes, the terms involving $E(U_t^2)$, $E(\epsilon_t^2)$, and $E(U_t\epsilon_t)$ were omitted in equation (15). If these terms are constant over time, then their omission will only bias the intercept term. However, as pointed out by Aradyula and Holt, the rational expectation of the variance will be constant over time unless the variances of the exogenous variables vary over time. In our case [see equation (13)], this implies that IV_t^* and YV_t^* must vary over time.

forecasts since actual output prices (and variances) are not known until three or four bimonths in the future. In this situation, assuming that regressors are contemporaneously uncorrelated with the disturbance terms (which seems reasonable, given the nature of the generated forecasts) and conditional upon the realizations of prices and variances, maximum likelihood estimators are consistent and asymptotically efficient and the usual test statistics hold. (See, e.g., Judge et al.) On the other hand, the errors-in-variables assumption that producers react to the true unobserved mean (and variance) seems unreasonable, except perhaps in the true rational expectation case. This model together with potential estimation and statistical inference problems is discussed in detail, e.g., by Pagan. However, in this framework no complete treatment of the estimation and inference difficulties has been developed to account for predictions and squared prediction errors as regressors in the context of autocorrelation (our case). Furthermore, no instrumental variables appear readily available to improve upon a situation where five- to eight-month-ahead forecasts together with their mean-squared forecast errors are already used to generate the price and variance predictors. Thus, if the stochastic regressors story fits what cattle producers do, then the empirical results can be interpreted as conditional upon the price realizations with the maximum likelihood estimators possessing all the usual desirable sampling properties. The more complicated errors-in-variables model would be inappropriate.

Naive, ARIMA, and Futures Models

Supply response functions as given by equation (1) were estimated for the naive expectations, ARIMA forecasts, and futures price models. The data were scaled to improve the accuracy of the estimation. Each of the four supply equations had significant first-order autocorrelation; hence, modified Cochrane-Orcutt procedures were used to obtain maximum likelihood estimates. Results are presented in table 1.

The coefficient on corn price was negative for all models and significantly different from zero based on asymptotic t ratios except for the model based on futures prices. This result indicates that higher feed costs result in lower production. For

Table 1. Estimates of the Supply Response for Naive, ARIMA, Futures, and Rational Expectations Models

	Price Expectations Models

feeder cattle price, the coefficient was not significant in any of the models, although it was positive for the naive and futures price expectations and negative for the ARIMA's. As Freebairn and Rausser point out, the insignificance of these results is not surprising given the high degree of correlation between fed cattle and feeder cattle prices. The simple correlation coefficients between expected fed cattle and feeder cattle prices are 0.94, 0.92, 0.93, and 0.81, respectively, for the naive, ARIMA (2,1,0) ARIMA (1,1,1) and futures equations.

A negative supply response to the expectation of fed cattle price occurred for both ARIMA models, and a positive response occurred for the naive and futures price expectations. However, none of the coefficients were significantly different from zero. Jarvis showed theoretically that short-run supply response to an increase in the price of cattle should be negative, although short-run steer and bull supply were positively sloped in his empirical analysis. In subsequent work, Paarsch showed that slight changes in the underlying assumptions of the theoretical model may lead to a positive supply response. Empirical results for short-run fed beef supply functions have been mixed; evidence has supported both negative and positive response, although the coefficients have often been statistically insignificant (Nelson and Spreen). Interestingly, in the research presented here the evidence to support either model is not overwhelming because the use of different expectations models in the supply response function may lead to opposite signs on the coefficient of expected fed cattle price.

If producers are risk averse, they should reduce production when expected variation in output price increases. The negative and significant coefficient on the variance of fed cattle price in both ARIMA models supports this hypothesis. The naive model also has a negative, although insignificant, coefficient, while the result for the model based on futures prices is positive and insignificant.

Based on the number of statistically insignificant coefficients of expected prices and variances, one might infer that expectations and risk are unimportant in fed beef supply response equations. However, this is not necessarily the case. Statistically significant partial F values were obtained at the 5% level for four of the six response models when testing that the coefficients on expected price and variance are simultaneously equal to zero. The partial F-statistic values for the naive, futures, ARIMA (2,1,0), ARIMA (1,1,1) and rational expectations models are, respectively, 0.89, 0.65, 5.26, 3.97, and 7.20. The critical $F(2,64)$ value, at the 5% level, is 3.14. The partial F-test for the adaptive model was not performed since the mean was already highly significant. Hence, only the naive and futures models yielded insignificant partial F values, and the shortcomings of these two models have already been discussed. Many of the insignificant coefficients were due, in part, to high multicollinearity among the explanatory variables; more will be said about these problems below.

The elasticity estimates of both the mean and variance of fed cattle price, together with their associated standard errors, are reported in table 2. Not only are the signs different, but the magnitudes of the elasticities may vary significantly as well. For example, the elasticities of expected price are quite different for the two ARIMA models: .150 and .051. However, the elasticities of the variance are quite similiar: −.144 and −.136. For the naive model, in which producers are using the least amount of information, the elasticity of supply response to expected price is a relatively large value of −.311. If expectations are based on future prices, own-price elasticity has a value of −.227.

Table 2 indicates that the standard errors are rather large for the expected means and vari-

Table 2. Elasticities of the Expectation and Variance of Fed Cattle Price

	Naive	ARIMA (2,1,0)	ARIMA (1,1,1)	Futures	Adaptive	Rational
Expectation	−.311	.150	.051	−.227	−.838	.707
	(.238)[a]	(.271)	(.227)	(.219)	(.071)	(.406)
Variance	.004	−.144	−.136	.003	.001	.102
	(.075)	(.061)	(.061)	(.438)	(.006)	(.167)

[a] Standard errors are reported in parentheses. They were calculated at the mean values of the respective variables, assuming as is often done that the expected price and quantity of fed beef ratios are exogenous. An alternative procedure would be to obtain standard errors by the bootstrap procedure.

ances in the various models. In order to determine if these large standard errors were resultant from, in part, multicollinearity problems, the simple correlation coefficients between the explanatory variables were obtained, auxiliary regressions were run by regressing each explanatory variable on all the remaining explanatory variables, and condition numbers were found (e.g., Judge et al.). The primary problem apparently is the high correlation between feeder price and expected fed price (simple correlation coefficients of over 0.9 in four of the six models). In addition the auxiliary regressions indicated a strong linear relationship among feeder price and the remaining explanatory variables and among expected fed price and the other independent variables [adjusted R^2 values of approximately 0.98 were found, for example, in the ARIMA (1,1,1), ARIMA (2,1,0) and rational expectation models]. Finally, condition numbers of over 200 were obtained for the time series and futures models. These measures indicate the source of some of the difficulties in estimating supply response with expected prices and risk terms explicitly incorporated into the models.

Table 3. Estimate of Supply Response for Adaptive Expectations

Independent Variables	Coefficients
Constant	2.504**[b]
	(16.96)[c]
Seasonal 1	.255**
	(4.910)
Seasonal 2	.211**
	(3.517)
Seasonal 3	.087
	(1.548)
Seasonal 4	.099
	(1.799)
Seasonal 5	.218**
	(4.486)
Corn Price[a]	−.105
	(−.892)
Feeder cattle price[a]	.676**
	(27.85)
Adaptive expectation of fed cattle price[a]	−1.096**
	(−11.77)
Adaptive variance of fed cattle price[a]	.002
	(.269)
Autocorrelation coefficient	.363**
	(3.454)

[a] The dependent and all independent variables are weighted sums of lagged variables where $\lambda = .66$ and $\gamma = 1.00$. (See equation (6) for specific expressions.)
[b] Double asterisk indicates significance of a two-tailed test at the .01 level.
[c] Values in parentheses are t-ratios.

Adaptive Expectations

Equation (6) must be estimated to determine a supply response with adaptive expectations. However, if the ϵ_t's are independently and identically distributed, then the V_t's follow a higher-order moving-average process. Hence, a combination of generalized least squares and a two-dimensional grid search over λ and γ was attempted, but computer computations were unsuccessful probably because of the complexity of the specification of the variance matrix for the V_t's. Alternatively, equation (6) was estimated using a maximum likelihood procedure with a correction for autocorrelation, and a grid search was performed over λ and γ.

Results are presented in table 3. The minimum error sum of squares was obtained when $\lambda = .66$ and $\gamma = 1.00$. This result gives an interesting interpretation to equations (2) and (3): Although producers may use a naive expectation of the variance of fed cattle price, they revise their expectation of the mean in an adaptive manner. A negative and highly significant supply response to expected price is observed. The coefficient on the variance of price is positive, but insignificant. Elasticities for the adaptive model (reported in table 2) are quite different from the previously discussed models. The largest negative elasticity, −.838, is observed for expected price; while for the variance, the elasticity is .001, which is closer to zero than any other model. For the coefficient on corn price, a negative but insignificant sign is observed. The coefficient on cattle price is positive and significant.

Rational Expectations

The supply and demand system implied by rational expectations is given by equations (14) and (15). Because there are twelve variables in the equations but only nine underlying coefficients to be estimated (a through i), there are three restrictions. This system, with its restrictions, can be written succinctly as

$$(16) \quad PCAT_t = \alpha_1 + \alpha_2 QCAT_t + \alpha_3 I_t + \alpha_4 Y_t + \eta_t,$$

$$(17) \quad QCAT_t = \beta_o^r + \sum_{i=1}^{5} \beta_i^r S_i + \beta_6^r PCN_{t-r} + \beta_7^r PF_{t-r} + \beta_8^r I_t^* + \beta_9^r Y_t^* + \beta_{10}^* IV_t^* + \beta_{11}^r YV_t^* + \beta_{12}^r COV_t^* + \epsilon_t,$$

Table 4. Reduced-Form Estimates of the Restricted Supply Response and Demand Equations for Rational Expectations

Supply		Demand	
Independent Variables	Coefficients	Independent Variables	Coefficients
Constant	3.509**[a] (8.039)[b]	Constant	−3.600 (−1.510)
Seasonal 1	.139** (2.977)	Quantity of fed cattle	2.265** (4.279)
Seasonal 2	.147** (3.482)	Index of other meats	.003 (.813)
Seasonal 3	.104** (2.815)	Per capita disposable income	−.033 (−.792)
Seasonal 4	.078* (2.208)

Corn price	−.355** (−3.202)		
Feeder cattle price	.109** (3.832)		
Mean of index of other meats	−.014 (NA)[c]		
Mean of per capita disposable income	−.005 (−.261)		
Variance of index	−.020 (NA)[c]		
Variance of income	−1.936* (−2.511)		
Covariance of income and index	.397 (NA)[c]		

Note: The value of the log-likelihood function is 12.26.
[a] Single asterisk indicates significance of a two-tailed test at the .05 level; double asterisk indicates significance of a two-tailed test at the .01 level.
[b] Values in parentheses are t-ratios.
[c] Values of the t-statistics were not available because these coefficients were not directly estimated due to the imposition of cross-equation restrictions.

where

$$\beta_8^r = \beta_9^r\alpha_3/\alpha_4;\ \beta_{10}^r = \alpha_3^2\beta_{11}^r/\alpha_4^2;\ \beta_{12}^r = 2\beta_{11}^r\alpha_3/\alpha_4.$$

Full information maximum likelihood estimates were obtained for equations (16) and (17) with and without the restrictions. Tests of the restrictions are often used to test the validity of the Muth rational expectations hypothesis. The likelihood ratio test rejected the hypothesis that the three restrictions jointly held ($\chi^2 = 11.34$ with three degrees of freedom). Thus, the data do not support the hypothesis that producers form expectations of the mean and variance of fed cattle price rationally.

The reduced-form estimates of the restricted supply and demand system are presented in table 4. In the supply equation, the coefficient on corn price is negative and significant as expected. However, as with adaptive expectations, the coefficient on feeder cattle price was significantly positive. The negative significant coefficient on the variance of income is an intuitively appealing result. Because beef is a normal good, we would expect that uncertainty about per capita disposable income may result in a lower quantity marketed. In the demand equation, the only statistically significant coefficient was for quantity of fed cattle. Unfortunately, its sign was positive, which is counterintuitive.

The rational expectations of the mean and the variance of fed cattle price were predicted from equations (10) and (13).[6] Similar to the naive, futures, and ARIMA models, the single equation supply response given by (1) was estimated with the predictions of the rational expectation of the mean and variance. This was done for two reasons: to have a direct comparison with

[6] Because $E(U_t^2)$, $E(\epsilon_t^2)$, and $E(U_t/\epsilon_t)$ are assumed constant over time, they were omitted from the estimation of the rational expectations variance in equation (13). Clearly, the estimate of the coefficient on the variance will be unaffected by this omission and only the estimation of the intercept will be affected.

the other estimates of supply response and to test the validity of the rational expectations model in a nonnested test. (This will be discussed in the next section.) The results are presented in the last column of table 1. All of the coefficients on input prices and expectations were insignificant. Corn price had a positive coefficient while feeder cattle price had a negative one. Positive supply responses to both the rational expectation of the mean and variance were observed. The largest positive elasticity of supply response with respect to the expected fed cattle price, .707, was observed for the rational expectations model as indicated in table 2.

Shonkwiler and Hinckley estimate that the bimonthly elasticity of placements of cattle in feedlots with respect to expected fed cattle price was 1.221. They suggest that these placements represent 600-pound feeder steers and heifers that will be fed for three bimonths. We would anticipate that the response of placements to expected price would be greater than that of fed cattle marketings because there is no problem of heterogenous production lags with the specification in terms of placements. Of course, placements three bimonths prior to marketing represent only a fraction of total fed cattle marketed. As expected, all of the elasticities estimated in this study are, in absolute value, smaller than Shonkwiler and Hinckley's estimates.

Nonnested Hypothesis Tests

Given the supply response functions estimated using each of the six models of price expectations, it would be useful to know which model gives the best specification and, hence, which price expectation model most precisely reflects actual expectations. Unfortunately, because the supply response functions are not nested (i.e., no one model is a more general specification of any other model), it is not possible to use common tests based on the F-statistic or likelihood ratio. It is possible, however, to test among these non-nested models by using the J-test suggested by Davidson and MacKinnon.[7]

Davidson and MacKinnon consider the case of the single equation, possibly nonlinear regression model, the truth of which we wish to test:

$$(18)\qquad H_0: y_t = f(X_t, \beta) + \epsilon_{ot},$$

where y is the dependent variable, X is a matrix of independent variables, β is a vector of parameters to be estimated, and the error term ϵ_{ot} is assumed to be $NID(0, \sigma_o^2)$. Suppose economic theory suggests an alternative hypothesis:

$$(19)\qquad H_1: y_t = g(Z_t, \psi) + \epsilon_{1t},$$

where Z is a matrix of exogenous variables, ψ is a vector of parameters to be estimated, and ϵ_{1t} is $NID(0, \sigma_1^2)$ if H_1 is true. Consider the possibly nonlinear regression

$$(20)\qquad y_t = (1 - \Phi)f(X_t, \beta) + \Phi\hat{g}_t + \epsilon_t,$$

where $\hat{g}_t = g(Z_t, \hat{\psi})$ and $\hat{\psi}$ is the maximum likelihood estimate of ψ. If H_o is true, then the true value of Φ is zero. By using a conventional asymptotic t-test, the validity of whether $\Phi = 0$ can be tested; this is called the J-test.

Because significant first-order autocorrelation was detected in all the models except rational expectations, it was necessary to modify the J-test. Under H_o (i.e., $\Phi = 0$), with a first-order autoregressive scheme, equation (20) becomes

$$(21)\qquad y_t = f(x_t, \beta) + \epsilon_{ot},$$

where $\epsilon_{ot} = \rho_o\epsilon_{o,t-1} + \nu_t$ and ν_t is a white noise process. Thus, in the J-test we need to correct for first-order autocorrelation using ρ_o, i.e., equation (20) is modified to

$$(22)\qquad y_t = \rho_o y_{t-1} + (1 - \Phi)f((X_t - \rho_o X_{t-1}), \beta) + \Phi\hat{g}_t + \epsilon_t,$$

where $\hat{g}_t = g(Z_t, \hat{\psi})$ and $\hat{\psi}$ is the maximum likelihood estimate of ψ obtained from the following first-order autocorrelation transformed equation

$$(23)\qquad y_t = \rho_1 y_{t-1} + g((Z_t - \rho_1 Z_{t-1}), \psi) + \epsilon_{1t}.$$

We corrected for autocorrelation in the estimation of ψ, but we did not use the AR structure to calculate the predicted values, $\hat{g}(Z_t, \hat{\psi})$. The idea is to get efficiency in the estimation of ψ, but not include the AR structure in an extended model used for calculating $\hat{g}_t$. The latter point is most important because if we were to use $(\hat{g}_t + \hat{\rho}_1\hat{e}_{1,t-1})$, i.e., predictions corrected for autocorrelation, as the "variable" for which Φ is estimated, we run the risk of a significant estimate of Φ only because of the AR disturbance structure.

The modified J-test given in equation (22) was used to test the null hypothesis that each of the models based on naive expectations, ARIMA

[7] Orazem and Miranowski also use nonnested testing procedures to compare different expectations hypotheses. However, their work involves acreage allocations in Iowa, does not include the variance or higher moments, and considers only one of the expectation regimes examined in this paper.

forecasts, and futures prices were true against each of the remaining models. However, in the adaptive model, $QCAT_t$ was not the dependent variable, yet the specification of equation (22) requires a predicted value of $QCAT_t$ for $\hat{g}_t$. Hence, $\hat{g}_t$ was obtained from the estimate of equation (6) as

$$\hat{g}_t = AQ\hat{C}AT_t - .33QCAT_{t-r}$$

since $\lambda = .66$ and $\gamma = 1.00$. For the rational expectations model, the predicted value of $QCAT_t$ was obtained from the estimate of equation (15).

To test the supply response function with adaptive expectations against each of the other models, the modified *J*-test was again used. However, as noted previously, the dependent variable in the adaptive model was $AQCAT_t$ rather than $QCAT_t$. Hence, $\hat{g}_t$ is the predicted value of $AQCAT_t$ and was estimated as

$$\hat{g}_t = QC\hat{A}T_t - .33\ QCAT_{t-r}.$$

It is not possible to use the *J*-test to test a model with a multiequation specification against a single equation model. Thus, to test the validity of the model based on rational expectations against each of the other models, the single equation supply response estimated with the rational expectations predictors of the mean and variance discussed previously was used.

In table 5, the results of the pairwise *J*-tests are presented. The truth of each of the models based on ARIMA forecasts, futures prices, and naive and adaptive expectations is rejected by each of the other models except adaptive expectations. The hypothesis that adaptive expectations is the true model is rejected by each of the other models except rational expectations. Hence, the *J*-tests do not support any one model in particular with perhaps the least evidence for the adaptive model. To provide information in addition to the *J*-tests, the within-sample root-mean-square errors were also calculated for each of the models. These values were .152, .154, .159, .159, .142, and .209 for the naive, ARIMA (2,1,0), ARIMA (1,1,1), futures, adaptive, and rational expectations models, respectively. The highest value was observed for the rational expectations model perhaps adding additional evidence to reject the hypothesis that expectations are formed rationally. Somewhat contrary to the results of the *J*-tests, the supply response based on adaptive expectations has the lowest root-mean-square error.

Conclusions

The empirical analysis leads us to conclude that no one expectations model dominates the rest. Thus, the evidence suggests that expectations are heterogenous rather than homogenous. Furthermore, a meticulous examination of the empirical results indicates that multicollinearity problems, especially between feeder prices and expected fed prices, may lead to many insignificant individual coefficients, causing the analyst to conclude that expectations play a minor role in fed beef response decisions. While we cannot completely rule out this interpretation, the partial *F* tests strongly indicate that taken together expected price and risk factors significantly influence fed beef supply decisions. These findings may be of considerable value for researchers who attempt to analyze supply response models.

As previously mentioned, researchers have suggested that expectations based on futures prices and ARIMA models may be quite similar to Muth's concept of rational expectations. This work gives clear evidence to refute this hypothesis. Not only does the sign of the supply response differ for these models, but elasticities are quite different as well.

Table 5. Pairwise Tests for Hypotheses

	Alternative Hypothesis	H_{A210}	H_{A111}	H_{NAIVE}	$H_{FUTURES}$	$H_{ADAPTIVE}$	H_{RE}
Tested Hypothesis:	H_{A210}		4.37**[a]	4.38**	4.28**	1.80	3.77**
	H_{A111}	4.71**		5.03**	4.83**	1.63	4.21**
	H_{NAIVE}	6.55**	5.63**		6.40**	.03	2.38*
	$H_{FUTURES}$	7.18**	7.04**	6.33**		−.26	2.42*
	$H_{ADAPTIVE}$	4.12**	4.22**	4.58**	4.96**		1.58
	H_{RE}	3.66**	3.66**	3.49**	5.10**	.98	

Note: Entries are ordinary *t*-statistics for ϕ in equation (22).
[a] Single asterisk indicates significance of a two-tailed test at the .05 level; double asterisk indicates significance of a two-tailed test at the .01 level.

This work provides strong evidence that researchers must be careful in their choice of expectations models when estimating supply response because signs and elasticities may be significantly different depending on which model is used. The results presented here also suggest that additional work is needed in both the theoretical and empirical aspects of the fed beef market. In particular, a rigorous theoretical model of heterogenous expectations needs to be developed and empirically tested. Additional empirical work correcting multicollinearity problems in supply response would be helpful. Further theoretical work in nonnested hypothesis testing would benefit researchers by enabling them to compare single and multiequation supply response models.

Comments and Replies

Profit, Supply, and Factor Demand Functions: Comment

John R. Conlon

In Lau and Yotopoulos (1972) a new method of estimating production relations was developed, building on Lau and Yotopoulos (1971). This method, bringing together estimates of profit and factor demand functions, was further developed in Yotopoulos and Lau to incorporate a test of rationality. Their method has since been applied by Yotopoulos, Lau, and Lin; Sidhu; Sidhu and Baanante (1979, 1981); Jamison and Lau; and Junankar (1980a, b, 1982). Because the assumption of rationality is so fundamental to economics, and because few tests of this hypothesis exist, the Lau-Yotopoulos method is very important. However, these studies rest on advanced economic theory and sophisticated econometrics, so it is easy to be intimidated by them. Sophisticated estimators, however, are not necessarily free from error.

In this comment, it will be shown that many of the results obtained in the empirical profit function literature—both those which seem to support farmer rationality and those which seem to contradict it—can be explained, regardless of farmer behavior, if the wage is measured with an error.

The dual-approach estimators under discussion regress profit accruing to fixed factors against quantities of these fixed factors and prices of variable factors. Thus, suppose that there is only one fixed factor, Z, and one variable factor, X (labor, say), and let Y be output. Suppose, further, that the observed real wage to X (deflated by the output price) is W^* and let observed normalized profit $= \pi^* = Y - W^*X$. Then the profit function regression will be

$$(1) \qquad \ln \pi^* = C_0 - \beta \ln W^* + \delta \ln Z + e_1.$$

This regression is usually estimated with a factor share regression,

$$(2) \qquad W^*X/\pi^* = \mu + e_2.$$

If wages are measured accurately and profit maximization holds, then β should equal μ. This seems to give us a test of economic efficiency.

It is shown in this note, however, that even if farmers are not maximizing profits, measurement errors in W^* will tend to shift ordinary least squares (OLS) estimates of β towards μ. Thus, OLS profit function estimates which seem to confirm rationality may actually be caused by spurious correlation due to inaccurate wage data rather than reflecting rational farmer behavior.[1] A similar result would hold for analogous cost function estimates.

Note that this differs from the usual effect of measurement errors on OLS estimates. In most cases, measurement errors simply bias the coefficient of the mismeasured variable towards zero. In the case of OLS profit function estimates, however, measurement errors can be much more deceptive because they tend to give the economist spuriously encouraging results.

The actual tests of profit maximization do not use OLS profit function regressions. Instead they use joint estimates of the profit function equation (1) with the factor share equation (2) using Zellner's seemingly unrelated regressions (SUR) estimator. This note therefore next shows that, even if farmers are maximizing profits (so β should equal μ), joint estimators in the presence of measurement errors yield estimates of β which are biased down from μ. Thus, the usual tests of profit maximization based on joint estimates are biased toward rejection (though the standard errors of the estimates are usually so large that profit maximization is rarely rejected in practice). It also follows that joint estimates of (1) and (2) with the restriction $\beta = \mu$ imposed should be biased.

Quiggin and Bui-Lan have emphasized the potential significance of measurement errors in profit function estimation. They point out that if true wages are relatively constant in a cross section because of, say, labor mobility, then measurement errors may constitute a large fraction of the variation in observed wage.[2] They also note that wage coefficients in profit function regressions are generally less strongly negative when SUR rather than OLS is used, and they conjecture that this may be related to measurement errors. Their discussion, however, is apparently meant only to be suggestive, and their wording is ambigu-

John R. Conlon is an assistant professor, Department of Economics and Finance, University of Mississippi.

The author is grateful to George Tolley, Yair Mundlak, Lars Peter Hansen, Keith Womer, John Johnson, Bashir Al-Abedalla, Bhaskar Das, and three anonymous referees for extremely helpful remarks. While their suggestions greatly enhanced the quality of this paper, they are, of course, not in any way responsible for remaining errors. The author would also like to acknowledge a University of Mississippi summer research grant which kept food on his table during the writing of an earlier draft of this paper.

[1] This includes as a special case the result of Fuss, McFadden, and Mundlak that when firms maximize profits, errors in measuring the wage do not bias OLS estimates of (1).

[2] Junankar (1987) and Deaton (1988) also argue that observed price variation may in part be due to measurement errors.

ous if not contradictory or misleading.[3] In this note, we therefore replace their brief discussion with a consistent model. In so doing we confirm what in Quiggin and Bui-Lan's paper was only an undeveloped suspicion, that measurement errors provide a consistent explanation of the peculiarities of previous results in this important field.

Measurement Errors in OLS and Joint Estimates of the Profit Function

In this section it is shown that measurement errors cause OLS estimates of the profit function to mimic results which would follow from profit maximization, even when farmers are not maximizing profits. It is then shown that, if wages are measured with an error, then the usual test of rationality, based on SUR estimates of the profit function jointly with the factor share equation, will tend to reject profit maximization, even if farmers are maximizing profits.

Let output, Y, be a Cobb-Douglas function of input quantity X, giving

$$(3) \qquad Y = AX^{\alpha}e^{u+v}.$$

Here the fixed factor of production Z has been excluded for simplicity. In addition, productivity shocks u and v have been included, where u is anticipated by the farmer before input decisions are made, v is not anticipated by the farmer, and u and v are assumed independent with zero mean. The form of the error is similar to that given by Mundlak and Hoch.

Let W be the wage to labor deflated by the output price. Then setting expected marginal product equal to the wage times a systematic farmer error k gives

$$(4) \qquad \alpha AX^{\alpha-1}e^{u} = \alpha(Y/X)e^{-v} = kW,$$

using v unanticipated and, so, independent of X and u, and using the approximation $Ee^{v} = 1$. The specification of irrationality through the multiplicative factor k follows Lau and Yotopoulos (1971) and the general literature; $k = 1$ implies that profits are maximized. Rearranging (4) gives

$$(5) \qquad WX = (\alpha/k)Ye^{-v}.$$

Now assume that the observed real wage differs from the true real wage: $W^* = We^{\epsilon}$, where ϵ is a proportional error in observation, and where W, u, v, and ϵ are all uncorrelated with one another. Assume also that X and Y are observed without error (errors in Y could be subsumed under v; a model in which the measurement error affects both X and W is considered in the next section). Observed normalized profit is then

$$(6) \qquad \pi^* = Y - W^*X = Y - WXe^{\epsilon}.$$

Using equation (5) now yields

$$(7) \qquad \pi^* = (1 - [\alpha/k]e^{\epsilon-v})Y;$$

so, taking logs, and using a first-order Taylor approximation around $\epsilon - v = 0$, gives

$$(8) \qquad \ln \pi^* = \ln (1 - [\alpha/k]) + \ln Y + (\alpha/[k - \alpha])(v - \epsilon).$$

Solving (4) for X, plugging into (3) and solving for Y yields

$$(9) \qquad Y = \alpha^{\alpha/1-\alpha}A^{1/1-\alpha}k^{-\alpha/1-\alpha}W^{-\alpha/1-\alpha}e^{(1/1-\alpha)u+v}.$$

Taking logs and plugging into (8) gives

$$(10) \qquad \ln \pi^* = \ln (1 - [\alpha/k]) + (\alpha/1 - \alpha) \ln \alpha + (1/1 - \alpha) \ln A - (\alpha/1 - \alpha) \ln k - (\alpha/1 - \alpha) \ln W - (\alpha/[k - \alpha])\epsilon + (1/1 - \alpha)u + (k/[k - \alpha])v,$$

which, combining the constant terms, becomes

$$(11) \qquad \ln \pi^* = C - (\alpha/1 - \alpha) \ln W - (\alpha/[k - \alpha])\epsilon + (1/1 - \alpha)u + (k/[k - \alpha])v.$$

In addition, combining (7) with $W^* = We^{\epsilon}$ and (5), and using a linear approximation gives, for the factor share,

$$(12) \qquad W^*X/\pi^* = (\alpha/[k - \alpha]) + (k\alpha/[k - \alpha]^2)(\epsilon - v).$$

It can be seen from equation (11) that variation in ϵ will cause log observed profit, $\ln \pi^*$, to be negatively correlated with log observed wage, $\ln W^* = \ln W + \epsilon$, even if the log true wage, $\ln W$, is constant. Thus, when $\ln \pi^*$ is regressed against $\ln W^*$, spurious correlation will occur, even if there is no variation in the true wage. Furthermore, this spurious correlation mimics the profit maximization case. To see this, note from equation (11) that the coefficient on $\ln W^*$ in (1) is, in large samples,

$$(13) \qquad \begin{aligned} \text{plim}\, \hat{\beta} &= \text{Cov}(\ln \pi^*, \ln W^*)/\text{Var}(\ln W^*) \\ &= -\Theta(\alpha/1 - \alpha) - (1 - \Theta)(\alpha/[k - \alpha]) \\ &= -(\alpha/[k - \alpha]) - \Theta[(k - 1)\alpha/(1 - \alpha)(k - \alpha)], \end{aligned}$$

where

$$(14) \qquad \Theta = \sigma_w^2/(\sigma_w^2 + \sigma_\epsilon^2).$$

If measurement errors form a large part of the variation in the observed wage, that is, if σ_ϵ^2 is large compared to σ_w^2, then Θ will be small, and the estimate of β in equation (1), as seen in equation (13), will approach $\alpha/[k - \alpha]$, which is the OLS estimate of μ in equation (2), as seen in equation (12). Thus, if (1) and (2) are estimated separately using OLS, the results tend to mimic the case in which profits are

[3] For example, in the passage intended to explain why estimates of the factor price coefficient are larger when OLS is used than when SUR is used, they apparently assume that these OLS estimates are themselves close to zero. They also seem to think that the SUR estimator will somehow take the problem of measurement errors "into account." See also footnote 7.

maximized. A similar result could be proven for analogous cost function estimates.

Most profit function studies, however, test profit maximization by using joint SUR estimates of the profit function (1) with the factor share equation (2). If β in (1) is significantly different from μ in (2), then the hypothesis of profit maximization is rejected. However, joint estimates using Zellner's SUR method will be inconsistent in the presence of measurement errors, as is now shown.

Assume for simplicity that firms actually maximize profits, so $k = 1$. Then, using $\ln W + \epsilon = \ln W^*$, (11) becomes

$$(11') \quad \ln \pi^* = C - (\alpha/1 - \alpha) \ln W^* + (1/1 - \alpha)u + (1/1 - \alpha)v.$$

In addition, (12) becomes[4]

$$(12') \quad W^*X/\pi^* = (\alpha/1 - \alpha) + (\alpha/[1 - \alpha]^2)(\epsilon - v).$$

It can then already be seen that SUR will be biased, because the error term in (12′) is correlated with the independent variable $\ln W^* = \ln W + \epsilon$ in (11′).

The SUR estimator, essentially, takes linear combinations of regression equations, so that the resulting error terms are uncorrelated with each other, and then regresses the resulting equations using OLS (with weights, but that does not matter here). Regressing the error term in equation (11′) against the error term in equation (12′) gives regression coefficient

$$(15) \quad \phi = -(1 - \alpha)\sigma_v^2/\alpha(\sigma_v^2 + \sigma_\epsilon^2).$$

Note that this coefficient is zero unless $\sigma_v^2 \neq 0$. Thus, the SUR estimate will differ from OLS in this model only in the presence of farmer-unanticipated productivity shocks. Also note that equation (15) suggests that ϕ should be negative, between zero and $(1 - \alpha)/\alpha$ in absolute value. Unfortunately, none of the studies reviewed here report ϕ.

Using the regression coefficient ϕ, Zellner's SUR estimator, applied to (11′) and (12′), is equivalent to estimation of the equation

$$(16) \quad \ln \pi^* - \phi W^*X/\pi^* = C' - (\alpha/1 - \alpha) \ln W^* + (1/1 - \alpha)(u + v) - (\alpha/[1 - \alpha]^2)\phi(\epsilon - v)$$

and equation (12′) separately using OLS, where the errors in (16) and (12′) are now uncorrelated with each other.[5]

Unfortunately, the error in (16) now contains ϵ, and so is correlated with the regressor $\ln W^* = \ln W + \epsilon$. In fact, regressing the right-hand side of (16) against $\ln W^* = \ln W + \epsilon$, and using (15) gives, for the joint estimator of β the value,[6]

$$(17) \quad \text{plim}\beta_{joint} = (\alpha/1 - \alpha) \cdot \left\{1 - \frac{1}{\alpha} \frac{\sigma_v^2/\sigma_\epsilon^2}{([\sigma_v^2/\sigma_\epsilon^2] + 1)([\sigma_w^2/\sigma_\epsilon^2] + 1)}\right\}.$$

Note that this is an "unrestricted" estimate because β_{joint} is not restricted to equal the factor share estimate from (12′). Since this estimate is biased, the estimate with the restriction $\beta = \mu$ should also be biased.

Thus, the SUR estimate of β in the profit function regression will be biased downward away from $\alpha/(1 - \alpha)$. Furthermore, β_{joint} can even be of the wrong sign. This contrasts with the usual case, in which measurement errors bias the coefficient towards zero but do not cause the coefficient to have the wrong sign. Finally, note that the estimate is biased only if σ_v^2, the variance of the farmer-unanticipated productivity shock, differs from zero. Otherwise the error terms in the profit function regression and the factor share regression are uncorrelated [see discussion below equation (15)].

The above is consistent with the pattern in the empirical literature observed by Quiggin and Bui-Lan, that estimates of the coefficient of log wage have generally been lower in absolute value when SUR rather than OLS has been used, or even of the wrong sign.

Other Specifications of Measurement Errors

The last section examined the effects of a certain type of measurement error in detail. That measurement error, which we will continue to call ϵ, affected the observed wage, W^*, and through W^* the expenditure on the variable factor, W^*X, while the quantity of the variable factor, X, was known without error. Suppose, however, that the economist measures expenditure on the variable factor accurately but has inaccurate data on the quantity of the variable factor, say $X^* = Xe^{\epsilon'}$, where ϵ' is a new type of measurement error. Suppose further that an estimate of the wage is obtained by dividing the accurately measured expenditure by the inaccurately measured factor quantity, X^*. Then this estimated wage will be mismeasured as

$$(18) \quad W^* = Expenditure/X^* = WX/(Xe^{\epsilon'}) = We^{-\epsilon'}$$

where $Expenditure = WX = W^*X^*$ is measured without an error.

Because expenditure on the variable factor is measured without error, the profit and factor share in profit are both measured without error. With only $\ln W$ in

[4] A consistent estimate of α together with the variances and covariances of the error terms in (11′) and (12′) should yield estimates of the error structure. Work in progress is considering this issue. Unfortunately, none of the studies reviewed report the covariances between the error terms.

[5] The fact that SUR does not affect the estimation of (12′) is a special case of a result in Revankar (1974).

[6] This formula can, maintaining certain assumptions, be generalized to the n-input case.

equation (1) affected by the measurement error ϵ', the spurious correlation discussed in the last section does not occur. Thus OLS estimates suffer only from the downward bias that usually occurs in the presence of errors in the measurement of the independent variable. Furthermore, since the measurement error ϵ' does not affect the factor share, and so, the e_2 error in equation (2), that error will be independent of the observed wage in equation (1), so joint estimation will not lead to any additional biases in this case.

Suppose, however, that both types of measurement error occur, so

$$(19) \quad W^* = We^{\epsilon-\epsilon'}, X^* = Xe^{\epsilon'}, \text{ and } W^*X^* = WXe^{\epsilon},$$

This would be the effect, for example, of independent errors in measuring expenditure and X^*, with the wage obtained as expenditure divided by X^*. In this case, results similar to those in the last section will occur. The only differences will be that OLS estimates of β in (1) will be biased toward zero somewhat, and that now there will be two reasons why e_1 from equation (1) and e_2 from equation (2) will be negatively correlated. First, the previous mechanism through v will still be in operation: profits will still depend positively on v [as in equation (11′)], and the factor share will still depend negatively on v [as in (12′)]. Second, since the presence of ϵ' biases the OLS estimate of β in (1) toward zero, some of the negative effect of ϵ on observed profits will be picked up by the error term e_1 in (1), so e_1 will be negatively correlated with ϵ. Therefore, because the factor share, and so e_2, will continue to be positively correlated with ϵ [as in (12′)], this second mechanism also induces a negative correlation between e_1 and e_2. The positive correlation between e_2 and ln W^* will then cause the SUR estimate of β to be biased downward, just as before.[7]

Conclusion

This comment uses Quiggin and Bui-Lan's hypothesis of large errors in measuring the wage to explain some of the phenomena observed in the profit function literature spawned by Lau and Yotopoulos (1972). Of course, measurement errors may not be the only possible explanation of this phenomena, and, in any case, the importance of measurement errors should vary from data set to data set. Nevertheless, a number of suggestions can be made on the basis of the results in this note. First, a significant negative coefficient on the wage in OLS estimates of the profit function should not be taken as evidence of the reliability of the data or model because such a coefficient can arise purely from measurement errors. Second, researchers should check for evidence of measurement errors. One such piece of evidence might be positive correlation between the error e_2 in equation (2) and the log observed wage because both should depend positively on the measurement error ϵ [see (12′); there will also be correlation between the wage and the factor share, however, if the true production function is not Cobb-Douglas]. Third, SUR estimates of the profit function should either not be used at all or should be used with extreme caution. Leaving aside the model developed in this comment, the consistency with which SUR estimates of the wage coefficient are less negative than the OLS estimates suggests that the assumptions of SUR are probably violated.

Finally, more work needs to be done to determine the importance of measurement and other errors (such as quality variation) in profit function studies and to develop consistent estimates in the face of these errors. A careful analysis of the error structure of equations (1) and (2), for example, should yield some information. In addition, Deaton's work, assuming all price variations in a given location are due either to quality variations or measurement errors, may suggest a fruitful direction for future research.[8]

Assessing Strategies for Control of Irrigation-Induced Salinity in the Upper Colorado River Basin: Comment

Brandt K. Stevens and Henry J. Vaux, Jr.

In their analysis of the cost effectiveness and relative cost shares of alternative salinity control strategies in the Grand Valley, Gardner and Young (GY) inadequately address two issues. First, it has been shown that cost-effective input incentives require both a water tax and an irrigation system subsidy, irrespective of the consequences for cost shares (see references below). Second, by neglecting the income effect associated with the assignment of water quality entitlements to irrigators, *GY* may underestimate the resultant salt loads. This comment addresses these two issues in turn.

Cost-Effectiveness and Input-Based Incentives

A review of the findings of Holterman, Griffin and Bromley, and Stevens (1988) with respect to the cost effectiveness of input-based incentives is useful. In these models, pollution is produced jointly with output and is determined by $g(X_i)$, where X_i is a vector of $i = 1 \ldots m$ inputs. Some inputs increase pollution, such as irrigation water, and others abate pollution, such as additional capital in improved irrigation systems; therefore,

$$\partial g/\partial X_i \gtreqless 0.$$

Pollution-reducing input incentives, defined as the vector S_i, can include a water tax or a water conservation subsidy and an irrigation system subsidy. An irrigation system subsidy, consistent with GY's analysis, can be denoted by $S_i = \alpha_i P_i$, $0 \leq \alpha_i \leq 1$, where α_i is the government's percentage cost-share of an irrigation system loan payment. For a given vector of incentives, the distribution of entitlements, where the amount of the entitlement is given by X_i^0 for $i = 1 \ldots m$, encompasses a range of net payments from a pure subsidy to a pure tax (Griffin and Bromley, Mumy). Under the status quo, irrigators receive a n subsidy (X_i^0 equals current input use). Irrigators pa a net tax if all rights are assigned to downstream use (X_i^0 equals zero). For an allocation of entitlemen between these two extremes, irrigators and dow stream water users share entitlements and pollutic control costs.

Entitlements can be changed through negotiatio and/or legal proceedings which, in the GY case, wou involve Upper Colorado Basin irrigators, dow stream water users, and the federal governmen However, the process for changing entitlements is bo lengthy and unpredictable, so irrigators have a stro tendency to view present entitlements as fixed. E titlements should therefore be treated as given (Gri fin and Bromley).

For a competitive profit-maximizing firm, a set m influent incentives exists whose cost-effectivene is identical to that of an effluent incentive, S, at t same level of pollution control (Griffin and Bromle Stevens 1988), when

$$(1) \quad S_i = S(\partial g/\partial X_i);\ S_i \gtreqless 0 \text{ when } \partial g/\partial X_i \gtreqless 0 \quad \text{for } i = 1 \ldots r$$

Two conclusions can be drawn from equation (1 First, cost effectiveness is not related to the direc ness or indirectness of an incentive, as asserted GY (p. 43). The indirect policy can be as cost e fective as the direct policy when each input's influe incentive is determined by the product of the efflue incentive and each input's marginal contribution pollution generated.[1] Second, the sign of the inp incentive can be positive, negative or zero, depen ing on the marginal effect of the input on pollutio Thus, a cost-effective influent strategy for reduci salt loads to the Colorado River requires increasi the opportunity cost of irrigation water with either water tax or water conservation subsidy while s

The research leading to this comment was supported by the University of California Salinity and Drainage Task Force.

The authors wish to thank Keith Knapp and two *Journal* reviewers for constructive comments, although the authors are solely responsible for any remaining errors.

[1] Equation (1) assumes equal transactions costs for effluent a influent incentives. However, the criticism of GY's view of c effectiveness is valid because their empirical model also assum equal ($0) transactions costs. Both types of incentives may ha similar information requirements for implementation (Stevens 198 p. 290–91).

Equation (1) also applies for a multicrop model (Griffin a Bromley). Stevens' (1982) empirical analysis with a multicrop mo shows that, chosen correctly, an influent strategy results in the sa social cost as an effluent charge.

multaneously subsidizing irrigation system capital.[2]

Although the data in tables 2–4 of GY suggest that an effluent incentive is more cost effective than influent incentives, this apparent contradiction arises because the influent incentives chosen by GY cannot be cost effective (compared to the salt tax). For example, table 2 of their paper implicitly assumes that the marginal effect of irrigation water or irrigation system capital on pollution is nil because either S_1 (the water tax) = \$0 or S_2 (the irrigation system subsidy) = \$0. In table 4, the tax/subsidy policies indicate a nonzero marginal effect for irrigation water and irrigation system capital. However, this is insufficient to ensure cost effectiveness because the vector of cost-effective influent incentives is uniquely determined by each input's marginal contribution to pollution evaluated at the desired salt load reduction. Some tax/subsidy pairs in table 4 may be cost effective, but this cannot be true of all the policies presented. For example, if a tax/subsidy of \$14/40% is cost effective, a salt load reduction of more than 91,400 tons requires an increase in both incentives (a higher water tax and a larger subsidy), not an increase in just the irrigation subsidy.

The social losses from an inefficient set of influent incentives may be considerable. A conservative (but rough) estimate suggests that the social costs of achieving a desired salt load reduction may be 25%–100% higher because the influent incentives are improperly chosen. This estimate is based on a comparison of the total social costs of the salt taxes from table 2 and the block water tax/irrigation system subsidies in table 4. The comparison is necessarily rough because the salt load reductions are unequal for the two types of incentive mechanisms.

According to GY, the advantage of a simultaneous tax/subsidy strategy lies with its ability to change the distribution of costs. "Combining cost-sharing mechanisms into a 'carrot and stick' approach provides flexibility to cost distribution. We tested irrigation system subsidies with both salt and water taxes and water conservation subsidies with water taxes . . . nearly any local cost share can be achieved by varying the level of the 'carrot' and/or 'stick'. . . . Pragmatically, this flexibility in cost distribution may be worth some efficiency loss and additional administrative expense" (p. 45).

The review of cost-effective influent incentives demonstrates that this view is incorrect for two reasons. First, a cost-effective influent strategy requires a water tax (or water conservation subsidy) and an irrigation system subsidy, irrespective of the consequences for relative cost shares and regardless of the distribution of entitlements. An irrigation system subsidy/salt tax policy or a water conservation subsidy/water tax policy cannot be cost-effective. Second, no trade-off between the goal of an acceptable distribution of pollution control costs and cost-effectiveness is necessary. Policy makers can achieve any distribution of pollution control costs by varying X_i^0 from current usage levels to zero without changing the cost-effective influent incentives. Equation (1) shows the vector of incentives is independent of the distribution of entitlements. For example, using a given two-tiered water pricing structure, such as \$4.00/\$15.80 per acre-foot, a change in entitlements (and different cost shares) occurs when different quantities of water, such as 3.0/1.25 acre-feet and 2.5/1.75 acre-feet, are available at the two prices. Policy makers may choose to change the distribution of entitlements, through, for example, the EIS process, to make the salinity control policy politically acceptable to all parties, including rent-seeking irrigators.

Income Effects of Assigning Entitlements to Irrigators

The asymmetry of pollution taxes and pollution subsidies has been well-documented theoretically (Kamien, Schwartz, and Dolbear; Porter; Baumol and Oates). According to Baumol and Oates, when the marginal incentive of a pollution subsidy and a pollution tax are equal, the subsidy lowers the average cost of production, whereas the pollution tax raises average costs. The subsidy therefore encourages entry by new firms, increasing industry output while industry emissions may rise or fall (relative to preregulation emissions). Although these studies pertain to effluent incentives, a formal proof of the income-effect asymmetry for influent incentives can be readily constructed. Such a proof is omitted here for brevity.

The practical significance of the income-effect asymmetry from assigning entitlements partially or entirely to irrigators is unclear. GY's model could be revised to analyze this potential problem; the discussion here provides a rough estimate of the income effect's impact on salt loads.[3]

Empirically, the income asymmetry would manifest itself as an increase in irrigated acreage or a shift in crop mix or both.[4] Intuition suggests an increase in irrigated acreage or shifts in crop mix would take place on marginal quality cropland. Furthermore, Caswell and Zilberman show that when growers pay the full costs of water-conserving irrigation technol-

[2] The water tax and water conservation subsidy have the same marginal effect on irrigation water use. However, the water tax distributes entitlements to downstream water users and the water conservation subsidy maintains the status quo distribution of entitlements to irrigators.

The analysis is restricted to the two influent incentives analyzed by GY; but, strictly speaking, cost effectiveness may also require incentives for other inputs, for example, irrigation labor.

[3] Feinerman, Letey, and Vaux; and Caswell and Zilberman predict increasing yields from adoption of irrigation systems that apply water more precisely. Hence, the region's output will increase and we focus attention on salt loads.

[4] A shift in crop mix may occur if an increase in net rents alters growers' responses to risk. Given the per-acre deep percolation losses in Leathers and Young, shifts in crop mix are likely to have a small impact on salt loads. The discussion therefore focuses on an increase in irrigated acreage.

ogies, (a) these technologies will be adopted more frequently on lower quality cropland and (b) irrigable acreage will increase as lower quality cropland is drawn into production. Assuming profit-maximizing behavior, growers may increase irrigated acreage when net rents on new acreage equal or exceed net rents on marginal acreage now in production, subject to factors such as risk considerations and crop rotation patterns.[5]

There are three reasons an increase in irrigated acreage is plausible. First, the two block water tax/system subsidies in table 4 that result in a net subsidy payment increase net rents 8%–10% of base rents ($225,000 to $244,000). Second, growers will have unused water rights resulting from the adoption of improved irrigation systems. Under a water tax/irrigation system subsidy strategy, irrigation water use falls for two reasons—the tax makes some water rights uneconomical and some water is conserved via irrigation system improvements.[6] Table 2 in GY shows technological conservation of at least 22,000 acre-feet (10% of baseline water use) for a system subsidy equal to or greater than 50%. Third, Leathers and Young (p. 36) note that Grand Valley's acreage base could increase by as much as 15% from renovating the region's drainage system for salinity control purposes. The increase in annual net rents from a favorable distribution of entitlements could be used to finance regional drainage system improvements.

A rough estimate of the income-effect's impact on salt loads can be computed, assuming irrigated acreage increases 4%–15%. The lower bound of 4% is based on the assumption that annual fluctuations in irrigated acreage are representative of the effect of assigning entitlements to irrigators and is approximately equal to the standard deviation of the mean irrigated acreage.[7] Leathers and Young's estimate of the acreage increase resulting from regional drainage system improvements is utilized as the upper bound. The deep percolation coefficients in Leathers and Young vary by crop, with an average deep percolation equal to .59 acre-feet per acre. If an additional acre-foot of deep percolation adds 5 tons of salt to the Colorado River, total salt loads do not increase from 237,350 tons, but salt loads would be 5,900–22,125 tons higher than predicted by their model. The income effect's environmental impact is approximately 4%–16% of the predicted salt load reduction for the two policies that increase net rents.

If distributing entitlements partially or entirely to irrigators is necessary to ensure political acceptance of salinity control policies, policy makers may wish to mitigate the additional salt discharges. Regulators should consider a requirement that growers (a) not cultivate any additional acreage and maintain current crop rotation patterns or (b) accept a reduction in water deliveries consistent with the performance capabilities of new irrigation systems. An increase in irrigated acreage is directly prohibited by the first policy and indirectly prohibited by the second policy. In either case, if water is not a limiting resource under present conditions, water conserved by improved irrigation systems would not be used on existing acreage or new acreage, thus preventing increased drainage and salt loads.

Each requirement may be difficult to implement. For example, some mechanism to accommodate normal acreage fluctuations may be necessary. In addition, although the Food Security Act of 1985 contains a sodbuster/swampbuster provision, a separate program specifically for Grand Valley may be required because planting new alfalfa, an important Grand Valley crop, is not considered sodbusting. Present institutions will need to be modified to allow reduced water deliveries. Grand Valley has six water distribution entities which hold water rights in trust for irrigators served; irrigation entities that hold riparian rights have seniority. Additionally, as GY note, this water could be reappropriated by other (perhaps agricultural) Upper Basin users under the Colorado River Compact of 1922. In spite of these potential problems, a reduction in water deliveries would provide a strong incentive for growers to manage improved irrigation technology to its full potential, ensuring that actual salt load reductions match policy makers' expectations.[8]

Conclusion

It is important to understand how the distribution of pollution control costs is affected by the distribution of entitlements. Buchanan and Tullock have shown that polluters tend to oppose the use of market incentives as a pollution control strategy because of incentive payments to environmental regulators. Altering the distribution of entitlements can reduce (total) incentive payments markedly, thereby providing some measure of political acceptability for incentive strategies. This comment demonstrates that whatever the distribution of pollution control costs that all parties would find acceptable, the allocation of entitlements necessary to achieve the desired cost-shares and the

[5] Growers may have criteria other than net rents on marginal acreage, or may face other constraints, that determine when and how much additional acreage would be planted as a result of a favorable distribution of entitlements.

[6] If growers continue to purchase their full water allocation, the cost savings from adopting improved irrigation systems would be reduced. However, table 2, part A, shows that the labor cost reduction from better irrigation systems is larger than irrigators' share of new system costs for any subsidy greater than 30%. Thus, growers still have an incentive to adopt (subsidized) irrigation systems even if they use their full water allocation.

[7] The mean irrigated acreage was computed from U.S. Bureau of Reclamation acreage data, 1975–84, and adjusted for the crop acreage base used in GY's model. The standard deviation of the mean acreage (after acreage base adjustment) is 2,039 acres.

[8] As noted, this technologically surplus water results from the adoption of improved irrigation systems. Because growers have already received an incentive—the irrigation system subsidy—for this water, selling diversion rights to downstream beneficiaries is inconsistent with the cost-effective influent incentives from (1).

cost-effective influent incentives are independent, not conflicting, policy problems. When entitlements are distributed such that irrigators receive net payments, an income effect asymmetry would occur. In this specific case, the potential of the income effect appears modest. Nonetheless, policy makers should be aware of this potential problem and may wish to consider preventive measures.

Assessing Strategies for Control of Irrigation-Induced Salinity in the Upper Colorado River Basin: Reply

Robert A. Young, Richard L. Gardner, and Edward W. Sparling

Stevens and Vaux (SV) raise two issues. First, they remind us that the cost effectiveness of an input (or influent) charge for pollution control can be identical to that of an effluent incentive at the same level of pollution control. Second, they contend that by not accounting for the income effect of subsidy approaches to pollution control, we may underestimate the resultant salt loads.

With regard to the first point, we agree that in a first-best neoclassical world modeled with continuously differentiable functions, the result they cite would hold. Central to the whole problem of nonpoint pollution is the impracticality of accurately measuring effluent. In a first-best world, and where economic efficiency is the sole objective, the effluent tax is for many analysts, the policy instrument of choice. However, given the difficulty of measuring effluent, practical policy analysis shifts attention to input incentives, on the assumption that certain inputs are both easily monitored and highly correlated with effluent.

An ideal input-based incentive scheme would require taxes or subsidies on all inputs affecting salt discharges. However, monitoring some important inputs, including management, labor and certain forms of capital, would be nearly as difficult as would keeping track of nonpoint salt discharges. Moreover, identification of an optimal incentive set would require precise knowledge of all transformations relating inputs to both outputs and discharges and of how risk enters into the producer's objective function.

Not having the resources to provide the ideal solution, we developed an admittedly second-best linear programming model that attempted to capture the relationships as well as possible. Since the typical farming patterns involves multiple crops, producer risk aversion is incorporated into the model with flexibility constraints. In addition, our model did not explicitly include labor and capital as variable inputs. Rather, their costs were deducted from revenues in the objective function.

In our study, the distribution of costs is equally important as economic efficiency. Hence, our strategy of analysis was to assess the cost effectiveness and distributional implications of a range of plausible policy options. In the process, we were willing to consider less than optimally efficient strategies. While we could have devised "efficient" influent incentive schemes, we did not do so, given the objective of our modeling exercise and the nature of our model. Because we were interested in representing workable incentives in the context of a second-best economic and policy environment, we made no attempt to construct first-best tax/subsidy schemes. It is certainly true that some of our incentive schemes were "inefficient," but that inefficiency is a cost of a second-best incentive scheme. Given these considerations, we feel no need to concede that our results provide other than what we sought: practical implications of plausible policies in an imperfect world.

The second point made by SV suggests that our analysis should be extended to consider "income effects" arising from of public subsidies to control pollutant emissions. By lowering the average cost of production, a subsidy may encourage entry by new firms or expansion by existing firms. Because of this potential expansion, total emissions may not fall by as much from a subsidy as expected. SV go on to acknowledge that "the practical significance of the income-effect asymmetry from assigning entitlements partially or entirely to irrigators is unclear." We fully agree. While we recognize the theoretical point, we would go further and say the point has little practical significance in our study area. First, the annual net rents would increase by less than $5 per acre. There is no particular reason to suppose that producers (who in this case are also households) would choose to invest that small amount to irrigate new lands rather than augmenting family consumption or paying off bankers. Second, even if producers considered so investing it, the minimal potential returns to new irrigated lands would be an effective deterrent. (The existence of positive net rents in the current situation is based on the fact that the presently irrigated area was largely financed by long since written-off public capital. New public subsidy to further irrigation development, while not inconceivable, seems unlikely.)

The length of SV's comment (more than half as long as our original article) may suggest to the reader that our policy conclusions are seriously damaged. We wish to conclude by reiterating that this is not the case. Our studies of the Colorado River Salinity Program can be encapsulated by these points. First,

Robert A. Young and Edward W. Sparling are a professor and an associate professor, respectively, Department of Agricultural and Resource Economics, Colorado State University. Richard L. Gardner is an analyst with the Division of Financial Management, Office of the Governor of Idaho.

in keeping with the tradition of western water policy, the economic benefits claimed for the federal salinity control program are significantly overstated, and the program is questionable on economic efficiency grounds. Second, the least-costly method of achieving significant salinity control in the Upper Colorado Basin is by retiring irrigated lands. Finally, the existing distribution of entitlements in the basin (which can be encapsulated as: The upper basin producers are entitled to continue to irrigate and discharge salt; the lower basin water users are entitled to improved water quality; and the federal taxpayer is entitled to pay the bill) warrants careful public reconsideration.

Separability Testing in Production Economics: Comment

Quirino Paris, Kenneth A. Foster, and Richard D. Green

Pope and Hallam (PH) proposed a test for indirect separability based on the rank of an appropriately defined matrix involving the bordered Hessian of the production function. This test is interesting and important, but its presentation obscures the main idea because the discussion, in the context of flexible functional forms, is marred by a crucial error. Blackorby, Primont, and Russell showed that a test for weak separability of flexible functional forms imposes strong and unwanted restrictions on a model's structure. After the publication of their paper, the consensus has been that a test for weak separability of flexible functional forms cannot be performed with the available functions. PH refer to this issue by stating: "This (test) moderates in some cases the criticism by Blackorby, Primont, and Russell" (p. 143). The reader is tantalized by this statement, but the rest of the paper does not shed any further light upon it.

PH discuss necessary and sufficient rank conditions for indirect separability but present also a lengthy elaboration of a necessary condition. The former set of conditions obviously provides a stronger test, and thus we focus our discussion upon it. Furthermore, PH's necessary rank condition as applied to the empirical example is wrongly stated and is inferior with respect to the stronger test.

We think that the contribution of PH can be stated in the following terms: The principal interest in the rank condition rests upon the possibility of testing the necessary and sufficient conditions for indirect separability. When not rejected, PH's rank condition, rank $[f_{\alpha\alpha}xf_{\alpha\alpha}](N_s, N_s^\theta) = 1$, implies indirect separability and, at least in two cases (generalized Leontief and quadratic functions), does not imply direct separability. Conversely, (in flexible functional forms), direct separability implies the rank condition for indirect separability, and this is the reason why this second test is subject to the criticism of Blackorby, Primont, and Russell. Thus, the rank condition applied to dual functions is noteworthy. However, its application in the context of flexible functional forms suggests that, for the translog function, its test is equivalent to the separability test originally proposed by Berndt and Christensen while, in the case of the generalized Leontief and quadratic functions, the two tests are substantially different. The numerical example chosen by PH is not suitable for illustrating the working of the necessary and sufficient rank condition which, furthermore, is erroneously implemented. The interesting question, therefore, is, are there other flexible functional forms (aside from the generalized Leontief and quadratic functions) for which the rank condition for indirect separability does not coincide with the conditions for direct separability? An answer to this question is conjectured in the conclusion.

Quirino Paris and Richard D. Green are professors of agricultural economics and Kenneth A. Foster is a research assistant in the Department of Agricultural Economics, University of California, at Davis.

The Rank Condition and Flexible Functional Forms

The discussion of page 148 is largely mistaken because an error of omission was made in computing the second derivatives of the general flexible functional form:

$$(1) \quad g(z) = \alpha_0 + \sum_i \alpha_i f_i(z_i) + \frac{1}{2}\sum_i \sum_j B_{ij} f_i(z_i) f_j(z_j), \quad B_{ij} = B_{ji}.$$

At the top of page 148, PH write the second derivative as

$$(2) \quad \frac{\partial^2 g}{\partial z_i \partial z_k} = B_{ik}\frac{\partial f_i}{\partial z_i}\frac{\partial f_k}{\partial z_k}.$$

Clearly, this second derivative is valid only for $i \neq k$ while the missing part is the derivative for $i = k$; that is,

$$(3) \quad \frac{\partial^2 g}{\partial z_i \partial z_i} = \frac{\partial^2 f_i}{\partial z_i \partial z_i}\left[\alpha_i + \sum_j B_{ij} f_j(z_j)\right] + B_{ii}\frac{\partial f_i}{\partial z_i}\frac{\partial f_i}{\partial z_i}.$$

The first term on the right-hand side (RHS) contains the α-parameters which are missing in PH's discussion of the necessary and sufficient rank condition. The representation of the rank condition for indirect separability, rank $[g_{zz}z\, g_{zz}](N_s, N_s^\theta) = 1$, where $N_s = (2, 3)$ and $N_s^\theta = (0, 1)$, reduces to the following:

$$(4) \quad \frac{\partial f_1}{\partial z_1}\frac{\partial f_2}{\partial z_2}\frac{\partial f_3}{\partial z_3}\sum_k [B_{31}B_{2k} - B_{21}B_{3k}]\frac{\partial f_k}{\partial z_k} z_k + \frac{\partial f_1}{\partial z_1}\left[\frac{\partial f_3}{\partial z_3}\frac{\partial^2 f_2}{\partial z_2 \partial z_2} z_2 B_{31}\alpha_2 - B_{21}\alpha_3 \frac{\partial f_2}{\partial z_2}\frac{\partial^2 f_3}{\partial z_3 \partial z_3} z_3\right] + \frac{\partial f_1}{\partial z_1}\sum_k \left[\frac{\partial f_3}{\partial z_3}\frac{\partial^2 f_2}{\partial z_2 \partial z_2} z_2 B_{31}B_{2k} - B_{21}B_{3k}\frac{\partial f_2}{\partial z_2}\frac{\partial^2 f_3}{\partial z_3 \partial z_3} z_3\right] f_k(z_k) = 0.$$

This general expression for the rank condition of indirect separability takes on different representations when applied to various members of the flexible functional family. For example, for the translog function, $f_i(z_i) = \log z_i$, the rank condition becomes

$$(5)\quad \frac{1}{z_1}\frac{1}{z_2}\frac{1}{z_3}\sum_k [B_{31}B_{2k} - B_{21}B_{3k}]\frac{1}{z_k} z_k + \frac{1}{z_1}\left[\frac{1}{z_3}\left(-\frac{1}{z_2^2}\right)z_2B_{31}\alpha_2 - B_{21}\alpha_3\frac{1}{z_2}\left(-\frac{1}{z_3^2}\right)z_3\right] + \frac{1}{z_1}\sum_k\left[\frac{1}{z_3}\left(-\frac{1}{z_2^2}\right)z_2B_{31}B_{2k} - B_{21}B_{3k}\frac{1}{z_2}\left(-\frac{1}{z_3^2}\right)z_3\right]\log z_k = 0.$$
